The detailed method has been described previously[1]. Bone marrow was obtained by aspiration from the sternum or iliac crest. Cell suspension cultures were prepared under aseptic conditions, using Hanks's solution and 40 per cent autologous serum as medium. ^{59}Fe in the form of $^{59}FeCl_3$ (Abbott Laboratories, Ltd., Montreal) (specific activity, 4·4–11 μc./μg) was added to the cultures to a final concentration of 0·01 μg/ml. The amount of iron added never exceeded the iron-binding capacity of the serum. Crystalline chloramphenicol (Parke Davis, Ltd., Montreal), erythromycin (Abbott Laboratories, Montreal) and tetracycline (Pfizer Canada Chemicals, Montreal) were dissolved in Hanks's solution and added, in various amounts, to the cell suspensions. The maximum concentration of the three antibiotics in the culture was 500 μg/ml., 500 μg/ml. and 100 μg/ml., respectively. The low solubility of the pure crystalline tetracycline did not allow the use of higher concentration. The volume of the cultures was 2 ml. in each tube and the total nucleated cell count varied from 2–4 × 10^6 per ml. The cultures were rotated at 12 r.p.h. for 24 h at 37° C. At the end of the incubation period, they were centrifuged, the cells washed three times with physiological saline and hæmolysed with distilled water at 4° C.

The radioactivity of the total hæmolysate was then measured in a well-type scintillation counter. From this, the total Fe uptake was calculated and expressed in μg Fe/erythroblast/h.

After centrifuging the tubes containing the hæmolysates at 3,000*g* for 15 min, the supernatant was removed and its radioactivity determined. From this, the amount of Fe incorporated into hæm was calculated and also expressed in μg Fe/erythroblast/h.

Cultures containing no added antibiotics, but prepared from the same marrow specimen, served as controls. In each experiment, cultures were prepared in duplicate.

As noted in our previous communication, when chloramphenicol was added to the cultures, iron uptake by the erythroblasts was slightly decreased, whereas iron incorporation into hæm was markedly decreased. Therefore, iron utilization, that is, the fraction of iron utilized for hæmoglobin synthesis in relation to the amount taken up by the cells, was significantly lower in the presence of chloramphenicol. This effect was proportional to the concentration of chloramphenicol in the culture, and the lowest concentration which gave consistent results was 500 μg/ml.

The addition of erythromycin to the cultures had a different effect. This was consistent in cultures of five different bone marrows, and Table 1 shows one representative experiment. The amount of iron taken up by the erythroblasts was strikingly reduced in the presence of erythromycin. Consequently, less iron was found in the hæmolysate. However, in contrast to chloramphenicol, in the erythromycin-treated cultures the percentage of the iron taken up by the cells which was incorporated into hæm was the same as in the controls. Thus, iron utilization was not altered in the presence of erythromycin. The effect of erythromycin depended on its concentration in the culture and 250 μg/ml. was found to be the smallest effective dose. 500 μg/ml. further reduced iron uptake, but had no influence on iron utilization.

Table 1. Effects of Erythromycin and Chloramphenicol on Iron Uptake and Iron Incorporation by Erythroblasts in Bone Marrow Suspension Culture

Incubation time 24 h. Values of a representative experiment	Control	Chloramphenicol 500 μg/ml.	Erythromycin 250 μg/ml.
Fe uptake, × 10^{-3} μg Fe/cell/h	1·59	1·12	0·61
Fe incorporation	0·79	0·21	0·39
Percentage of iron uptake incorporated into hæm	49·7%	18·8%	63·9%

The effect of tetracycline on erythroblasts was studied in 14 bone-marrow cultures. When 50 or 75 μg/ml. was present in the medium, the iron uptake and incorporation by the erythroblasts were not altered as compared with the controls. When 100 μg/ml. tetracycline was used, the uptake of iron by the erythroblasts was decreased in four of seven cultures but, as with erythromycin, the percentage of iron which was incorporated into hæm was the same as in the controls. Hence, both erythromycin and tetracycline decreased iron uptake but had no effect on iron utilization by erythroblasts in these bone-marrow cultures. No relationship could be found between the susceptibility of the cultures to the toxic effect of these agents and the hæmatological status of the patients from whom the bone marrows were obtained.

These observations indicate that chloramphenicol, erythromycin and tetracycline do not have identical effects on erythroblasts cultured *in vitro*. Chloramphenicol

slightly diminished iron uptake by the erythroblasts and interfered markedly with iron incorporation into hæm. On the other hand, both erythromycin and tetracycline depressed iron uptake by the cells. The mechanism of this effect is not clear, but, as tetracycline is known to be a chelating agent[3], a possible explanation is that it binds iron, thus making it less available for the cells. Of the iron taken up by the erythroblasts, the same percentage was incorporated into hæm as in the control cultures. Since this step is related to hæm synthesis, it seems that, in contrast to chloramphenicol, neither erythromycin nor tetracycline interferes with this synthesis in the erythroblasts. Erslev and Iossifides[2] did not find this different pattern of behaviour *in vitro* and, therefore, concluded that there was a discrepancy between the *in vivo* and *in vitro* observations. In contrast, the difference in the action of these drugs *in vitro* in the experiments reported here may explain their different behaviour *in vivo* in relation to the hæmic cells. Also, in our experiments, tetracycline affected erythroblasts to a lesser degree than did erythromycin or chloramphenicol, which may be related to its lower concentration in the cultures.

The effective *in vitro* concentration of the three drugs in relation to their *in vivo* therapeutic blood level was also different. The 500 μg/ml. concentration of chloramphenicol is 10–15 times[4], the 100 μg/ml. tetracycline is 20–40 times[5,6] and the 250 μg/ml. erythromycin is 50–100 times[7,8] the average effective therapeutic blood level. Lower concentrations of erythromycin and tetracycline, corresponding to 10–15 times their effective therapeutic blood level, had no measurable effect in the cultures. The fact that relatively higher concentrations of tetracycline and erythromycin were necessary to cause an adverse effect *in vitro* may also reflect that the hæmic cells are less sensitive to these drugs.

Finally, the fact that the effects of the three antibiotics on iron metabolism *in vitro* were different suggests that their antimicrobial action may also be different. This is in agreement with Brook[9], who suggested that, although their action on bacteria is assumed to be similar, based on the inhibition of protein synthesis, this cannot be more than a superficial similarity, in view of their completely different chemical structure. It must be recognized, however, that the action of a drug on a bacterium, and its action on the human cells, may be quite unrelated.

In summary: (*a*) Both erythromycin and tetracycline decreased the iron uptake by the erythroblasts, but had no effect on the utilization of iron for hæm synthesis. This indicates that, in contrast to chloramphenicol, these antibiotics did not interfere with hæm synthesis under the same experimental conditions. (*b*) The difference between the effects of these antibiotics *in vitro* may be related to their different behaviour *in vivo* on the hæmic cells.

IMMUNOLOGY

Suppression of Experimental Allergic Encephalomyelitis in Rats and Chickens treated with Reserpine

Previous investigations have shown marked suppression of delayed hypersensitivity reactions, prolongation of skin homograft survival, and impairment of antibody production in rats treated with reserpine[1]. Moreover, this *Rauwolfia* alkaloid was regularly found to produce thymic involution. This communication is an extension of these investigations, and deals with the effect of reserpine on the development of experimental allergic encephalomyelitis in the rat and chicken.

Adult male albino rats weighing 220–260 g from a randomly bred colony were treated with intraperitoneal 0·5 mg/kg injections of reserpine ('Serpasil', Ciba, Basle) for 17 consecutive days. Three days after the beginning of treatment all rats were injected with an emulsion containing fresh normal rat spinal cord and complete Freund's adjuvant[2]. Each rat received a single inoculation of 0·1 ml. of this antigen–adjuvant mixture in the left hind foot-pad. Control animals were treated with 17 injections of saline, and immunized with spinal cord adjuvant mixture as described for reserpine-treated rats. Animals were observed daily for the onset of clinical signs of disease. Those rats which showed paralysis or ataxia were killed on the day of onset of symptoms; the remaining rats were killed 19 days after immunization. Paraffin sections of cerebrum, cerebellum, medulla and three levels of spinal cord were prepared, and stained with hæmatoxylin and eosin. Histological changes were graded from 0 to +++[2]. Rats from both experimental and control groups were weighed every three days. At autopsy the thymus was also weighed.

Rhode Island Red chickens were treated with 2 mg/kg reserpine intraperitoneally every three days, beginning one day after hatching. At eight weeks, each chicken received foot-pad injections of homologous spinal cord adjuvant mixture as described elsewhere[3]. Control chickens of exactly the same age were immunized in an identical manner. Reserpine-treated and control birds were skin-tested 14 days following immunization; for this purpose 0·1 ml. containing 50 μg of chicken spinal cord lipid, obtained by petroleum-ether extraction, was injected into the left wattle. The right wattle was injected with 0·1 ml. of a 1 : 5 dilution of old tuberculin. The reactions were read at 24 h, and graded from 0 to +++ on the basis of œdema, induration and discoloration of the wattle. Sections of cerebrum, cerebellum, medullary bulb and spinal cord at three levels were stained with hæmatoxylin and eosin, and lesions were classified from 0 to +++[3]. Thymic lobes, spleen and bursa of Fabricius of all chickens were weighed at the end of the experiment.

The ability of reserpine-treated rats to develop experimental allergic encephalomyelitis was strikingly suppressed (Table 1). Eight of 10 rats injected with 0·5 mg/kg of reserpine showed no histological changes in the central nervous system, whereas 8 of 12 controls exhibited definite lesions characteristic of disease, and two rats of the latter group developed paralysis.

Table 1. Suppression of Experimental Allergic Encephalomyelitis in Rats treated with Reserpine

Group	No. of rats	No. of rats with encephalomyelitis* 0	+	++	+++	Average weight Thymus (mg)	Body (g)
Reserpine-treated (0·5 mg/kg)	10	8	1	1	0	90·0	129·7
Control	12	4	3	3	2	217·3	160·0

* Average severity of lesions observed in spinal cord, medulla, cerebellum and cerebrum.

Table 2. Suppression of Experimental Allergic Encephalomyelitis in Chickens treated with Reserpine

Group	No. of chickens	No. of chickens with encephalomyelitis*				Average weight (g)			
		0	+	+ +	+ + +	Thymus	Bursa	Spleen	Body
Reserpine-treated (2 mg/kg)	9	2	4	3	0	1·49	1·07	1·71	642·8
Control	12	0	2	1	9	3·30	2·60	2·58	1,156·0

* Average severity lesions observed in spinal cord, medullary bulb, cerebellum and cerebrum.

Table 3. Delayed Hypersensitive Reactions to Chicken Spinal Cord and Old Tuberculin in Reserpine-treated Chickens

Group	No. of chickens	No. of chickens with reaction at 24 h							
		Spinal cord lipid				Old tuberculin			
		0	+	+ +	+ + +	0	+	+ +	+ + +
Reserpine-treated (2 mg/kg)	9	8	1	0	0	5	4	0	0
Control	12	4	5	3	0	0	5	4	3

Repeated injections of reserpine regularly produced a marked involution of the thymus. The architecture of the thymic tissue was altered: cortical areas showed pronounced atrophy, and their cellular make-up, which normally consisted of densely packed thymocytes, was largely replaced by reticulum and epithelial cells. The average body-weight of reserpine-treated animals was less than that of controls; but treated animals were all in good condition and did not require artificial feeding. There were no signs of alimentary tract disturbances in these rats.

Only partial suppression of experimental allergic encephalomyelitis was observed in chickens injected with reserpine and killed 19 days after immunization (Table 2). However, histological quantitation of lesions found in various parts of the central nervous system revealed that the disease was more severe in controls than in chickens treated with reserpine. Three control chickens developed paralysis, whereas the clinical signs of disease were not observed in reserpine-treated birds. There was an involution (or slower development) of thymus, spleen and bursa of Fabricius in chickens injected with reserpine. Although there was a loss in body-weight in those birds, they did not show any obvious physiological and behavioural abnormalities. Chickens treated with reserpine and tested for delayed hypersensitivity 14 days following immunization with allogeneic spinal cord showed markedly impaired delayed wattle reactivity to chicken cord lipid and old tuberculin (Table 3).

The development of experimental allergic encephalomyelitis can be affected by a variety of factors including salicylates[4], cortisone and ACTH[5], alkylating agents[6], 6-mercaptopurine[7] and radiation[8]. The results presented here introduce a new member to the group of agents which suppress immunological potential or reactivity. Thus, reserpine is capable of impairing the evolution of an auto-allergic disease in rats and chickens. However, these findings do not imply that the mode of action of reserpine on the immunological capability of the animal's body is similar to that exerted by various antimetabolites, and that its effect should include mechanisms proposed for different types of drug-induced tolerance. Differences in responsiveness of different species to reserpine[9] may be responsible for less-striking suppression of experimental allergic encephalomyelitis in chickens when compared with the suppression obtained in rats.

Chronic treatment with reserpine of animals and chickens regularly results in involution of lymphoid organs such as thymus, lymph nodes, spleen and bursa of Fabricius, and causes profound cellular changes in those tissues (unpublished results). These findings may, therefore, provide a cellular basis for the impaired immunological reactivity of reserpine-treated animals. Bruscha[10] found in patients injected over a long period with a large dose of reserpine that a temporary drop in the eosinophil and monocyte count occurs. In addition, reserpine causes marked inhibition of the growth of a lymphoid tumour in mice[11], although this effect appears to be mostly non-specific[12].

Whether reserpine diminishes immunological capacity directly, or indirectly through its action on lymphoid tissues, or whether this alkaloid acts by releasing active substances such as 5-hydroxytryptamine and catecholamines from tissues is not known. Alternatively, these mediators may be necessary for the expression of auto-allergic lesions and other immune manifestations. Since one of the well-studied actions of reserpine is the depletion of brain serotonin stores, as well as the action on those brain regions known to control ACTH secretion[13], it is pertinent to consider whether this central effect is in any way related to the findings reported herein. It may be assumed that reserpine is interfering with the 'central control of immune response' by acting either on the brain, or on neuronal and endocrine pathways that monitor the immunologically competent tissues. The participation of the central nervous system in the expression and maintenance of immunological potential has not been investigated so far.

HISTOLOGY

Birefringence of the Spermatozoan Tail

THE motility of the spermatozoan tail depends on the contractility of its protein fibrils, which resemble myosin threads[1]. It is not surprising, therefore, to find that the tail is birefringent. This birefringence is difficult to demonstrate by the usual means, but is easily shown by special staining, combined with the use of elliptically polarized light (EPL). The stain is chromosome red ('Michrome No. 1091'). This is haplofavioxanthic acid, a special compound of acid fuchsin, sun yellow and violamine 3*B*. It has the effect of intensifying the anisotropy of already birefringent substances, particularly with EPL[2,3].

I first saw this phenomenon in paraffin sections of rat testis, fixed in formalin and cut at 8 or 10μ. These sections were stained for 5 min in a solution of chromosome red (0·8 g), acetic acid (2 ml.) and water to 100 ml. The birefringence of the sperm tails was seen both in the seminiferous and in the epididymal tubules. In the latter it was in strong contrast to the non-birefringence of the epididymal ciliariform processes or other cilia, prepared and examined in the same way. Since all anisotropic elements appear coloured in EPL, the colour depending on their orientation in the field, the helical form of the spermatozoan tail is easily demonstrated by the colour change as the helix changes direction in its course from the neck onwards. It is more readily seen with an oil-immersion than with a dry objective, although the birefringence of groups of spermatozoa is easily perceived with a low-power objective.

The combination of myosin content and birefringence thus makes the spermatozoan tail the equivalent of a fibril of smooth muscle. The intensity of colour seen is just that of smooth muscle examined under similar conditions. An investigation into the stage of spermatozoan development at which the phenomenon is first observable is in progress.

HISTOCHEMISTRY

Uptake of Tetracycline by Human Bone *in vitro*

SINCE the demonstration by Milch *et al.*[1-3] that tetracycline is taken up in newly-formed bone after injection into the living organism, the tetracyclines have been used widely in the study of bone formation, especially by the technique of double labelling[4]. It has lately been shown by Harris *et al.*[5], comparing the uptake of tetracycline *in vivo* with the uptake of radioactive calcium, that, besides the distinct uptake in the calcification front, there is also an uptake in other parts of the bone, not related to new bone formation. In a communication to *Nature*[6], one of us showed that a diffuse uptake of tetracycline can be demonstrated in bone grafts, with the histological appearance of dead bone. We have, therefore, investigated the uptake of tetracycline in bone devitalized by different methods.

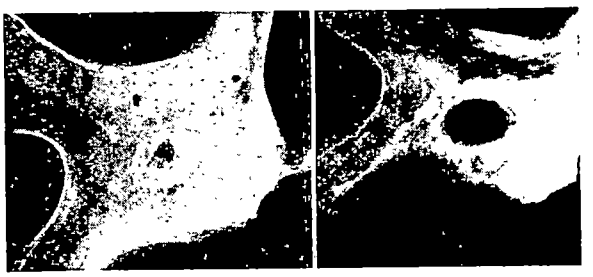

Fig. 1. Cancellous bone treated by alcohol during two weeks storage. Undecalcified specimen examined under ultra-violet light on the right and the corresponding radio-micrograph. Note the uptake on surfaces, in the demarcation zone and inside the bone in inverse relation to calcium density

Human bone, cortical or cancellous, was treated by freezing at −20° C for 2 weeks, boiling or storing in alcohol, or was kept as fresh bone. To each specimen was added a solution of 10 mg of 'Ledermycine' in 100-ml. citrated human plasma for 24 h. The bone was then rinsed in running tap water for a period of 48 h. The specimens were then fixed in formalin, dehydrated in alcohol and embedded in methyl-methacrylate. After cutting and grinding the bone specimens to a thickness of about 50μ, radio-micrographic pictures were taken, and fluorescence was observed in ultra-violet light, using a 'Reichert' filter *GG* 9/1 mm + *OG* 1/1·5 mm.

From the photographs (Figs. 1 and 2), showing the fluorescent picture and the corresponding radio-micrograph of cancellous and cortical bone, it is seen that mineralized dead bone takes up tetracycline on every surface. As in living bone, there is a greater uptake on the growing part, in the zone of demarcation, within the osteoid seam. In non-growing surfaces, like osteons which show edge-sclerosis on corresponding radio-micrographs, or in resorption cavities, there is a limited uptake. Besides this surface incorporation, there is also a diffuse uptake, which is more prominent in cancellous than in cortical bone: this is demonstrated by comparing Fig. 1 with Fig. 2. In all cancellous specimens, there is an inverse relationship between the mineralization of the bone and the degree of labelling with tetracycline. The results are not affected by the method of devitalization of the specimens.

Thus, the uptake of tetracycline by bone is evidently not dependent on the activity of living bone cells, or on the integrity of the physical properties of the intercellular components, which are greatly modified by boiling and storing in alcohol[7]. Tetracycline incorporation cannot be directly related to calcium uptake, because there were no free calcium ions in the citrated plasma used (citrate would be more likely to liberate calcium from the bone[8]). The localization of tetracycline inside the bone supports the conclusion that tetracycline uptake is not confined to growing surfaces. Its peculiar distribution might be explained by a diffusion phenomenon[5,6], but tetracycline uptake in low-density areas is less in cortical than in cancellous bone. Tetracycline staining is present whenever

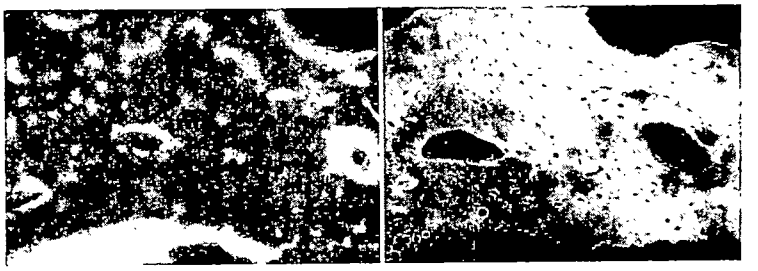

Fig. 2. Cortical bone refrigerated at 20° C and thawed after two weeks. Note the surface uptake, including the resting osteon, with the so-called edge-sclerosis and the fluorescent band corresponding to the growing osteon's calcification front. The fluorescence inside the bone is fainter and uniformly distributed. Ultra-violet light photograph and radio-micrograph as in Fig. 1

calcification is imminent, and its intensity is perhaps related to the rapidity of the calcification that follows.

Histotopochemistry of Ascorbic Acid in Tendon Fibres

From investigations with the electron microscope, it has been reported that the precursors of collagen fibrils are formed within the cytoplasm of fibrocytes[1]. It follows that the sites of formation of the fibrils and those of the synthesis of collagen are identical. Hydroxyproline, which is a characteristic acid of collagen protein, originates from proline under the action of L-ascorbic acid[2].

For this reason we believe that determination of the distribution and concentration of ascorbic acid in the connective tissue, for example in the tendon, would suggest where hydroxylation of proline takes place and where the tropocollagenous cells, which are the basic elements of the fibrils, are formed.

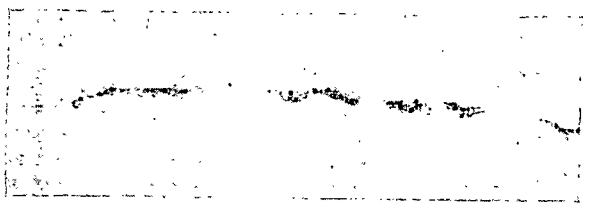

Fig. 1. Black granules of metallic silver in the tendon cells indicate L-ascorbic acid, which takes part in the conversion of proline to hydroxyproline

In this work L-ascorbic acid was determined in isolated fibres from the tail tendon of male albino Wistar rats, 4 months or 28 months old. The method of Giroud and Leblond, applying silver nitrate to metallic silver, was used. The granules occurring in the positive reaction are not granules of vitamin C but granules of metallic silver[3].

It has been found that in isolated tendon fibres of both the younger and the older rats the granules of silver are deposited only in the cytoplasm of fibrocytes; the remaining fibrillar structure is negative.

The occurrence of L-ascorbic acid in the tendon cells which intensively produce collagen supports the suggestion that conversion of proline to hydroxyproline occurs within the cytoplasm of the cells, and that a collagen molecule may there be built up from the individual amino-acids.

PATHOLOGY

An Unidentified Virus which causes the Rapid Production of Tumours in Mice

In the course of routine passage of Moloney's leukæmogenic virus (MLV) plasma was collected from a leukæmic rat (Chester Beatty Institute outbred albino strain) which had been inoculated with MLV-containing mouse plasma when new-born. After storage at −70°C for three months the rat plasma was diluted 1 in 30 with Hanks's saline and passed through a 'Selas 02' filter, tested and found impervious to *Esch. coli*. The filtrate was injected into 15 new-born *BALB/c* mice, as a test of potency. Only 6 survived to weaning. On the 32nd day 5 had tumours at or near the injection site, and all had grossly enlarged spleens. Usually mice inoculated with MLV remain symptomless until they show the characteristic signs of leukæmia after 8 weeks.

Further samples of the same stored plasma filtrate were injected into new-born *BALB/c* mice, and Chester Beatty albino (outbred) and hooded (inbred) rats. Twenty-eight of 35 mice, and 1 of 13 rats, killed and examined *post mortem* had tumours, and all had splenomegaly.

The pathology of the disease is being examined: the result of early observations are as follows. The animals commonly die of splenic rupture, as in Friend or Rauscher disease. The histology of the spleen and the blood smears are similar to those of Friend disease. There is gross proliferation of reticulum cells in the spleen, and reticulum cells and erythroblasts appear in the blood. The tumours are of two main types, either solid and firm, or cystic and filled with blood. The former arise in the subcutaneous tissue and peritoneum, sometimes attached to the muscle of the abdominal wall, thorax, or diaphragm; their position suggests development at or near the site of injection or along the needle track. They are anaplastic sarcomata consisting of pleomorphic and spindle cells, some very large, invading and disrupting adjacent tissues. The latter may occur anywhere in the subcutaneous space or peritoneal cavity, and often in relation to lymph nodes. They are angiomatous tumours consisting of multiple dilated sinuses which are filled with blood and debris, and lined with cuboidal cells which often form ingrowths into the lumen.

Recent experiments have shown that of a number of animals injected with sarcoma virus (SV) when new-born 30/46 *CB* hooded rats developed gross splenomegaly, and 16 had sarcomas of the diaphragm or other sites. 4/9 cream and 5/19 golden hamsters have developed sarcomas, also mainly situated on or near the diaphragm. Many of the rats and hamsters had large thin-walled cysts at lymph node sites containing either clear or blood-stained fluid.

Two of 5 attempts to transplant sarcomas in *BALB/c* mice were successful, and the cell line is now in its fifth passage. All recipients have developed splenomegaly.

Tissues of tumour-bearing mice and plasma of injected rats were tested by inoculation into *BALB/c* mice for the presence of tumour-producing virus (Table 1).

'Selas 02' filtrates of tumour homogenates or plasma induced rapid development of tumours and splenomegaly in mice inoculated when 1–7 days old, in some cases as early as 12 days after injection. As the age of injection increased, the incidence of tumours declined, but that of splenomegaly remained high. Fifteen mice inoculated at 112 days all developed splenomegaly, but only two developed tumours.

One to 2 day-old Chester Beatty albino rats were injected with the original plasma filtrate. Their plasma was collected at 8, 30, and 54 days, and injected into 1–3-day-old *BALB/c* mice. Mice which received the 30- and 54-day samples developed tumours and splenomegaly in 12–15 days. Those which received the 8-day sample

Table 1

* These mice died with generalized lymphatic leukæmia.

remained healthy for 70 days, when they developed the typical signs of MLV-induced leukæmia—an indication that Moloney virus was still present in the virus preparation (Table 1).

The possibility that the tumours produced might be due to polyoma virus was considered. Certain differences were already apparent: for example, no parotid or kidney tumours were seen in the injected mice, and polyoma tumours have never been reported as early as two weeks after inoculation. Certain specific tests were performed. (1) Active preparations of SV produced no cytopathic effect in mouse embryo tissue cultures, and did not agglutinate guinea-pig red cells in the cold. (2) The sera of mice bearing sarcomata did not inhibit hæmagglutination by polyoma virus. (3) In two separate tests samples of SV were found to be ether-sensitive. These results make it very unlikely that the tumours produced are due to polyoma, or any closely related virus.

The presence of other viruses in the SV preparations is being considered. As indicated above, MLV is almost certainly still present. The type of splenomegaly, and its short latent period, suggests this may be due to Friend, or possibly Rauscher, virus. In this connexion it is noteworthy that *BALB/c* mice may carry the Rauscher virus in a latent form[1]. Since none of these leukæmogenic viruses has been shown to produce sarcomata of the type reported here it appears likely that they are due to a hitherto unidentified virus. The Schmidt–Ruppin derivative of Rous sarcoma virus rapidly produces tumours in small mammals, and is ether-sensitive—in these respects it resembles SV. This virus is being tested for. Another possibility is that the observed effect may be the result of some kind of synergism between two or more viruses (as, for example, between the Moloney or Friend virus and mouse hepatitis virus[2], and this possibility is also being investigated.

I thank Dr. M. H. Salaman and Dr. K. E. K. Rowson of this Department, and Dr. R. J. C. Harris of the Imperial Cancer Research Fund Laboratories, for their advice. I also thank Dr. F. C. Chesterman (also of the Imperial Cancer Research Fund) for his advice concerning the histological preparations. Mr. R. Evans helped with the tissue culture and Miss J. M. Burke with histology and hæmatology.

Ink Blue as a *p*H Indicator for Certain Biological Systems

The observation that commercial blue-black ink poured on to the uncolonized agar of a Petri dish culture of *Trichophyton mentagrophytes* became discoloured in the region of the dermatophyte, but not of a contaminating mould, led to further investigation of this phenomenon. A solution of one of the major constituents of blue-black ink—ink blue (supplied by Imperial Chemical Industries as 'Ink Blue AS' crystals)—behaved similarly, and it seemed probable that the clearing was caused by either *p*H or *Eh* conditions around the colony. The response of Ink Blue to changes of this kind was initially examined in aqueous solution.

The absorption maximum of a 0·005 per cent solution of ink blue in water, measured on a Unicam '*SP*600' spectrophotometer, was 610 mμ. It was found that a standing period of at least 5 min was required before the solution attained stability of optical density, and 25 min was necessary when 1 ml. of a 0·05 per cent solution was added to 10-ml. buffer at *p*H 7·8. Thereafter the absorption remained constant.

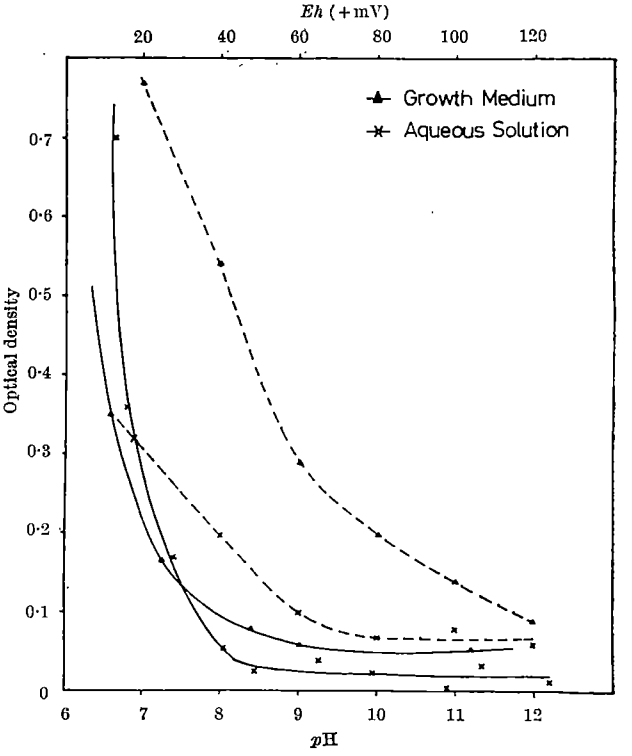

Fig. 1. Discoloration of ink blue solutions with increasing *p*H, ——, and *Eh*, - - - -

The behaviour of ink blue solution over the *p*H range 3·5–12·21 was investigated by adding 1 ml. of a 0·05 per cent solution to 5 ml. of an appropriate buffer. After it had stood for 30 min the optical density at 610 mμ was measured against a distilled water blank. The *p*H values were checked on a direct-reading *p*H meter (E.I.L., model '23*A*') using reference electrode '*RJ*23' and glass electrode '*GG*23'. The change from blue to colourless occurred between *p*H 7·38 and 8·04.

The influence of *Eh* on the discoloration of ink blue was examined by adding 1-ml. quantities of a 0·05 per cent solution to 5 ml. of appropriate dilutions (0·01–0·08 M) of molar sodium thioglycollate solution, giving a range of *Eh* of −100 mV to +120 mV, and the optical density of each sample was measured at 610 mμ against a distilled water blank (Fig. 1). *Eh* was measured on the E.I.L. *p*H meter using the platinum metal electrode '*EPT*23' and reference electrode '*RJ*23'. There was a progressive clear-

Table 1. Correlation of Ink Blue Discoloration by Culture Filtrates with Actual *p*H and *Eh*

	Uninoculated	*Trichophyton mentagrophytes*	*Microsporum canis*	*Epidermophyton floccosum*	*Aspergillus terreus*
Optical density	∞	0·14	0·47	1·5	∞
Eh (mV)	−160	−100	−100	−130	−130
*p*H (direct)	5·2	7·4	6·3	5·6	4·2
*p*H equivalent to optical density	< 5·5	7·45	6·32	5·6	< 5·5
Visual colour	Blue	Clear	Pale blue	Blue	Blue

ing of the solution from deep blue at the initial value of −100 mV (with no reducing agent), to complete discoloration at +60 mV.

The behaviour of ink blue was found to be modified when dissolved in a liquid growth medium. Batches of medium, containing 1 per cent mycological peptone ('Oxoid') and 4 per cent glucose in the appropriate buffer, were prepared in 5-ml. quantities and the optical density of each sample after the addition of 1 ml. of 0·05 per cent ink blue was determined as in aqueous solution. There was a general shift of the *p*H curve caused by the buffering action of the peptone, and discoloration occurred at a lower *p*H than in aqueous solution. The medium was pale blue at *p*H 6·5 and complete discoloration had occurred at *p*H 7·2 and above.

The influence of *Eh* changes in liquid growth medium was investigated in a similar manner to aqueous solutions. Unlike the *p*H curve, *Eh* was not modified by the constituents of the medium, but the optical density of each sample was higher (Fig. 1). The initial sample, with an *Eh* of −80 mV, was deep blue, and progressive clearing occurred until, at +100 mV, discoloration was complete. A change of 180 mV was thus necessary before complete clearing could be recorded.

These characteristics of uninoculated ink blue liquid medium were then correlated with the discoloration phenomenon caused by fungal growth. Samples were removed from liquid cultures of four species of fungi after 11 days' culture on unbuffered glucose–peptone medium. Each sample was centrifuged to remove any mycelium and the *p*H and *Eh* of 5 ml. of the supernatant were recorded. To each sample was added 1 ml. of a 0·05 per cent aqueous solution of ink blue, and, after standing 30 min, the optical density at 610 mμ was measured against a water blank (Table 1).

The measurements of optical density, when compared to the *p*H curve, showed that the *p*H equivalent to each optical density corresponded well with the actual *p*H. The change in *Eh* due to the growth of the fungus was in no case sufficient to cause discoloration, none of the fungi causing a difference of more than 60 mV when compared to uninoculated medium.

It was, therefore, concluded that the discoloration of ink blue solution by the three dermatophytic fungi tested was a reflexion of the release into the medium of alkaline metabolic by-products. A variety of dermatophytes have been shown to liberate alkali into their culture medium[1] but no evidence has been obtained for the presence of any strongly reducing conditions[2]. As non-keratinophilic fungi tend to turn media acid, these facts suggest that ink blue might be of value in the differentiation of keratinophilic and non-keratinophilic fungi. It would also appear that ink blue could be a useful non-toxic *p*H indicator in biological systems where *p*H changes in aqueous solutions occur in the region of 7·4–8·0

BIOLOGY

Maintenance of Oyster Cells *in vitro*

The examination and control of oyster (*Crassostrea virginica* Gmelin) pathogens have received much impetus in recent years with the recognition of *Haplosporidium costale* Wood and Andrews, '*MSX*' an undescribed haplosporidian, and *Dermocystidium marinum* Mackin, Owen and Collier along the Atlantic and Gulf coasts of the United States. Research in the problems of isolation, identification and control of oyster pathogens could be facilitated if techniques for the culture of oyster cells were available.

Comparatively little work has been done with molluscan cell and organ maintenance. Probably no true molluscan tissue cultures have been established, if one considers a tissue culture to be an *in vitro* system where the cells undergo mitosis and from which sub-cultures may be formed. Maintenance investigations of molluscan tissues have been conducted by Gresson[1], Gatenby *et al.*[2] and Cameron[3].

In the work recorded here it has been found that oyster cells can be maintained for as long as 42 days in hanging-drop slide cultures. 1-mm² pieces of mantle margin were used as explants. Each piece was washed through six changes of sea-water containing 0·5 mg of streptomycin/ml. and 0·3 mg penicillin *G* (sodium salt)/ml. As determined by Zobell's marine bacterial agar medium[4], this technique was 80 per cent effective in obtaining sterile explants.

Crab (*Callinectes sapidus* Rathbun) plasma was used as a substrate for attachment of the explants and cells. The plasma forms a clear, firm and sterile coagulum when filtered through a 0·45μ 'Millipore' filter. 'Millipore' Filter Corporation's Swinny hypodermic adapter with filter and prefilter was used. No anticoagulant was used; all manipulations were conducted at 0° C in silicone-coated instruments to prevent premature coagulation. It was found that the cells and explants attached more readily and for longer periods of time to the coagulum than to the cover slip itself. The cultures were maintained between 23° and 25° C.

The medium which proved to be the most successful is given in Table 1.

Table 1

NaCl	$46{\cdot}66 \times 10^{-3}$ moles
KCl	$1{\cdot}02 \times 10^{-3}$ moles
$CaCl_2$	$1{\cdot}10 \times 10^{-3}$ moles
$MgCl_2{\cdot}6H_2O$	$1{\cdot}16 \times 10^{-3}$ moles
$MgSO_4$	$2{\cdot}86 \times 10^{-3}$ moles
$NaHCO_3$	$0{\cdot}25 \times 10^{-3}$ moles
'T.C. Yeastolate' (Difco)	0·100 g
Glass-distilled water	100·0 ml.

Eighty per cent of the above solution, 10 per cent oyster blood, 5 per cent female gonad extract, and 5 per cent adductor muscle extract—all by volume. 0·1 mg streptomycin and 0·06 mg penicillin/ml.

The physiological saline portion of the medium is after Cameron[5]. A hydrogen ion concentration of *p*H 7·2–7·4 was used. The osmotic pressure was adjusted by dilution with glass-distilled water or evaporation to within 2–3 atmospheres of the blood osmotic pressure in the tissue donor. The blood was found to range between 22 and 25 atmospheres; osmotic pressures were determined by freezing-point depression.

The extracts were prepared by grinding the selected organs with a volume of Cameron's sea-water which equalled three times the weight of the organ. The homogenizer consisted of a test tube with ground-glass interior and a close-fitting ground glass plunger. The homogenate was centrifuged at 5,000*g* for 20 min and the supernatant was utilized as the extract. Only female oysters which exhibited opaque gonadal tissue were used as a source of gonadal extract. No attempt was made to measure the condition of the gonads. The work was conducted during April–August 1962, which encompasses the major spawning period.

In the 40 cultures established, using the foregoing medium, the patterns of cell behaviour were consistent. Amœbocytes migrated out from the explant 30–40 min after establishing the culture. The cells were apparently identical with the lymphocytes and leucocytes found in oyster hæmolymph[6]. The predominant cell type was the leucocyte by a factor of about 100. They were greatly variable in size and form, measuring at the longest axis 9·0–26μ. Spherical cells were found suspended in the drop of medium and were probably dead or inactive leucocytes. They outnumbered the amœboid cells about 5 : 1 in most cultures.

A peak of migratory activity was reached at the end of the first 24 h, but cells continued to migrate out from the explant at a lesser rate during the entire culture period, as could be seen from the fact that the inactive spherical cells were replenished after each renewal of the medium. Fresh medium was added every third day. As early as 5 h after establishment of the culture, pseudopodia of adjacent amœbocytes came in contact, forming monolayer networks of cells. After 48 h an area of about 40–60 mm² around the explant was usually covered with the loose network of cells. Thereafter the monolayer remained about the same in terms of area covered and density of cells. There appeared to be no cellular connexions between the explant and the monolayer.

No evidence of mitosis was found using Delafield's hæmatoxylin and Feulgen's fuchsin. Probably all the cells found in monolayers had their origin in the explant. Histological sections of the mantle reveal connective tissue cells which resemble the amœbocytes of the monolayers in terms of cellular form, size, granules and reaction to the two stains mentioned above. However, whether mitosis occurred in the explant to a significant degree was not determined. Although large numbers of unattached, inactive leucocytes were washed away with each change of the medium, the explant did not seem to decrease in volume, as would be expected.

After a maximum of 42 days, the network was seen to break down into individual cells which became spherical and lost their attachment to the substrate. Many of the cells lysed several hours after assuming a spherical shape. The degeneration of the cultures was sometimes very gradual, beginning after the culture was 30–40 days old and lasting for 3–5 days thereafter. The cultures were destroyed after there ceased to be any amœboid cells. Ninety per cent of the explants were still alive at the end of the experiments, as evidenced by the ciliary action of the epithelial cells.

In 5 cultures out of the 40 which were established, leucocytes migrated close to the periphery of the drop and attached to cover slip. There they formed a dense, round group of spherical, inactive cells from which radiated a network of cells and their protoplasmic processes. The network was more filamentous in appearance than the network which formed around the explant. There appeared to be no difference between the two networks except that, in the former case, the cells originated from the periphery of the clump of leucocytes while, in the latter case, the network had no direct connexion with the explant.

A similar pattern of cell behaviour could be obtained by simply placing an explant in a drop of sea-water in a hanging-drop culture system. However, the monolayers which were formed were no more than 20 per cent as large as those mentioned here and they did not last longer than 4–5 days as monolayers.

Grace's medium[7] has been shown to provide a satisfactory environment for growth of insect tissues *in vitro*. In attempts to use a modified form of the medium to culture oyster mantle, the medium was found to be no better than sea-water controls. The only modification in the medium was to substitute Cameron's medium, twice as concentrated, for the physiological saline suggested by Grace.

Influence of Fungicides on the Tomato and Growth of *Botrytis cinerea* Pers

SPRAYS of maneb (manganese ethylene *bis*dithiocarbamate) or zineb (zinc ethylene *bis*dithiocarbamate) increased the incidence[1] of grey mould of tomatoes, caused by *Botrytis cinerea* Pers., but adding thiram (tetramethylthiuram disulphide) or 'Dyrene' (2,4-dichloro-6-*o*-chloroanilino-*s*-triazine) to either of the above sprays prevented infection[2]. Apparently maneb and zineb either stimulate the growth of *B. cinerea* or induce a change in the tomato favouring growth of the fungus. To investigate this phenomenon the effect of these fungicides and other chemicals on the germination and growth of *B. cinerea* was examined, and tests were made for total-ninhydrin-staining compounds and carbohydrates in exudates washed from the surface of treated tomato leaves and fruit.

Fungicidal activity was determined by the slide germination method[3] using spores of *B. cinerea*. Assays were also made with mixtures of the juice of ripe tomatoes and fungicides. Standard and tomato juice controls were run with each test. The lengths of 20 germ tubes were recorded at each dilution where germination occurred. The results given in Table 1 show the average of 2 or more dilution tests. Additional assays were conducted using manganese and zinc salts at concentrations of Mn^{++} or Zn^{++} equivalent to that contained in maneb and zineb test solutions. The effect of casamino-acids, dextrose, lævulose and sucrose on length of germ tube was also determined.

Table 1. EFFECT OF FUNGICIDES ON THE GROWTH OF GERM TUBES OF *B. cinerea*

Fungicides	ED_{50} (p.p.m.)	Concentration showing stimulation (p.p.m.)	Average percentage increase in length of germ tubes over control

* Calculated as glycine. † Calculated as glucose. ‡ *D*, 'Dyrene'; *M*, maneb; *T*, thiram; *Z*, zineb; *C*, control.

Three 5–6-week-old tomato plants, variety Stokesdale, were sprayed with either 'Dyrene', maneb, thiram or zineb at 1,600, 8,000 and 16,000 p.p.m. of active ingredient. After 36 h the fourth and after 120 h the fifth leaves distal from the apical meristem of the 3 plants at each dose were washed 3 times in 200 ml. of distilled water to collect released nutrients. Ten harvested ripe tomatoes, variety 'Michigan-Ohio', sprayed at 1,600 or 8,000 p.p.m. fungicide were similarly washed after 36 h. Plants and tomatoes sprayed with water served as controls. The solutions were then centrifuged at 9,000 r.p.m. for 10 min and the supernatant concentrated to 5 ml. at 45° C. The concentrated solutions were tested for total-ninhydrin-staining compounds[4] and total carbohydrates[5]. Similar foliage tests were conducted with exudates collected from plants 36 h after spraying with manganese and zinc salts. Following vacuum concentration of these manganese and zinc salt exudates, they were passed through 'Dowex 50' *W–X8* (ref. 6) cationic exchange resin columns, to remove Mn^{++} and Zn^{++} which interfere with the ninhydrin test. The amino-compounds were eluted with ammonium hydroxide, reconcentrated and tested for amino-acids. The solutions tested for carbohydrates passed through the 'Dowex 50'. It was not necessary to remove the cations in exudates from the fungicide treatments. All tests were performed at least twice.

Maneb and zineb stimulated the growth of germ tubes of *B. cinerea* whereas 'Dyrene' and thiram did not have this effect (Table 1). The addition of juice of ripe tomatoes reduced the toxicity of the four fungicides. The greatest reduction in fungitoxicity occurred with the metal-containing fungicides. This suggests a possible chelation of the metal ions by a component in the tomato juice, since Ludwig *et al.*[7] found that the metal ion promotes the formation of isothiocyanate (to which the *bis*dithiocarbamates may owe their fungitoxicity). Some stimulation of the growth of *B. cinerea* can be attributed to the cations Mn^{++} and Zn^{++} (Table 2). Casamino-acids and sugars gave considerable stimulation.

In 58 per cent of the exudates from leaves sprayed with fungicides there was an increase in total-ninhydrin-staining compounds and in 92 per cent of the exudates there was an increase in total carbohydrates (Table 3). With maneb the largest increases recorded for total amino-acids and carbohydrates were 689 and 328 per cent, respectively. The increases were not always associated with the highest fungicide concentration or longest exposure time. The 1,600 p.p.m. treatment was considered equivalent to one field spray of 2 lb. per 100 gal./acre and the higher concentrations to repeated applications. Slight increases in amino-acids in tomato fruit sprayed with maneb and zineb at 8,000 p.p.m. were recorded but there was little or no change in the carbohydrate content in the exudates of sprayed fruit. Part or all of the increase in amino-acids in exudates could be attributed to metal ions in maneb or zineb since the amino-acid content of exudates from leaves sprayed with manganese and zinc salts were found to be increased 1,023 and 690 per cent, respectively. The salts did not increase total carbohydrates.

These results indicate that maneb and zineb may increase the susceptibility of tomatoes to *B. cinerea* by stimulating the growth of the fungus and by the release of nutrients from the host favourable to fungal growth. 'Dyrene' and thiram also release nutrients from the plant but probably do not increase susceptibility to *B. cinerea* due to their greater fungitoxicity to this fungus.

In vitro Culture of Seedlings of *Striga senegalensis* Benth

It is difficult to germinate the seeds of most obligate, phanerogamic root parasites. Saunders[1] demonstrated that certain factors exuded from the roots of maize could stimulate the germination of *Striga asiatica* (witchweed) seeds. Further development of the seedling occurs only when a host root is penetrated.

In the work recorded here the seeds of *Striga senegalensis* (*S. hermonthica*) were germinated in sterile nutrient media to discover whether the seedlings could grow in the absence of a host.

The seeds were sterilized in 1 per cent sodium hypochlorite solution for 15–20 min and incubated on moist filter paper in Petri dishes for 10–12 days in darkness (25° ± 2° C) for moisture pretreatment[2]. The cultures were raised on nutrient media employing Knop's or modified Murashige and Skoog[3] minerals. Varying amounts of sucrose or other sugars were used as the source of carbon. An aqueous exudate of the host (*Sorghum vulgare*) roots was incorporated into the media to initiate and stimulate the germination of *Striga* seeds. The host exudate was filter-sterilized before adding to the rest of the medium in order to avoid heat-destruction (during autoclaving) of its germination factor[1]. The *p*H of the medium was adjusted to 5·5–5·8 and the medium was gelled with 1·2 per cent Difco 'Bacto' agar. About 100–200 seeds were inoculated on the surface of the agar slant in each culture tube. Cultures were kept in darkness at 25° ± 2° C or in natural daylight in the laboratory or greenhouse.

After growth for 30 days in darkness on Knop's medium containing 1 per cent sucrose, the seedlings attained the maximum size of 2 mm having six pairs of leaves. The length of shoot and number of leaves decreased with increase in sucrose concentration. Adventitious roots with root hairs were produced by seedlings in media having no sugar or lower concentrations of sucrose.

However, the medium containing higher concentration of mineral salts (Murashige–Skoog minerals[3]) and 2 per cent sucrose supported the best growth. Within 30 days

Fig. 1. Four months and nine days old cultures of *Striga senegalensis* seedlings on Murashige and Skoog minerals + *A*: 1 per cent mannose, *B*: 1 per cent glucose, showing flowering in light (× *c.* 0·13)

the seedlings were 18 mm long, had nine pairs of leaves and produced numerous adventitious roots with root hairs.

In other trials with Murashige–Skoog minerals, it was demonstrated that fructose, glucose, mannose, maltose, galactose, lactose, xylose and raffinose can also serve as carbon source for *Striga* seedlings. Ribose, sorbose, rhamnose and mannitol were not effective in growth.

By transfer to large culture tubes, seedlings could be grown for several months on Murashige–Skoog minerals–sugar medium. In this new medium there was no root exudate—only water, agar, minerals and sugar. In light, the seedlings became intensely green and flowered after 4–5 months in culture (Fig. 1). Due apparently to lack of fertilization, they did not produce viable seeds.

To my knowledge, this is the first report of successful culture *in vitro* of seedlings of *Striga*. Worsham *et al.*[4] and Williams[5] reported that kinetin and gibberellic acid stimulated the shoot apices of germinated *Striga* seedlings to elongate beyond the cotyledons, but with no further growth. Williams[5], therefore, suggested that *Striga* seedlings probably depend on the host for a supply of growth factors. Success in the present investigation in obtaining development of normal *Striga* seedlings on media containing only mineral salts and sugar indicates that Williams's[5] suggestion may not be tenable, at least for *S. senegalensis*. It appears that *Striga* seedlings can synthesize their growth factors once they are supplied with mineral salts and a suitable sugar. The enhancement of growth of seedlings on Murashige–Skoog minerals–sugar medium as compared with Knop's minerals–sugar medium could be due to the former's high mineral salts content, or ammonium nitrogen or both. On the basis of my experimental results, it appears that *Striga senegalensis* depends on its host only for minerals and sugar and not for more elaborate substances.

I thank Prof. Ernest Ball of the University of North Carolina, Raleigh, and Dr. P. C. Joshi for their advice.

ENTOMOLOGY

Independent Development of the Male Gonads and Vasa Deferentia, and the Genitalia of the Australian Earwig, *Labidura riparia truncata* (Dermaptera : Labiduridae)

L. r. truncata Kirby is the Australian-wide form[1] of the cosmopolitan earwig *Labidura riparia* (Pallas). Snodgrass[2] lists literature dealing with the development of the genitalia in several insect orders. His description of the process in the Dermaptera is largely based on the account given by Qadri[3] for *Forficula auricularia* L. (Forficulidae). Snodgrass points out that it is generally held that the genitalia develop from the primary phallic lobes and that the terminal ampullæ of the vasa deferentia are commonly associated with the lobes.

The position in *L. r. truncata* is, however, quite different, for the internal reproductive organs and the genitalia develop independently of each other (at least, during the first three of the five nymphal instars). Their development has been investigated by means of serial sections of the entire abdomen, cut at 5μ and stained with Mallory.

In a specimen at three days (first instar) the testes were found to be in much the same position as in adults: dorso-lateral, near the midgut, and surrounded by fat-body. Each was cigar-shaped and consisted of the usual two follicles. The contents corresponded to the germarium and an early stage of the zone of spermatocytes of a mature testis. Posteriorly the two follicles coalesced and the testis ended blindly, with no sign of a vas deferens.

At this stage, the genitalia consisted of a pair of conical phallic lobes, pointing posteriorly, fairly close together, fused basally and lying in the genital chamber above the ninth sternum. The phallic structure consisted of a solid mass of uniform undifferentiated cells invested with a cuticular intima. There were no ducts associated with the phallic organs. The lining of the genital chamber joined the base of the phallic structure just in front of the phallic lobes, so that they lay outside the body-wall.

In a third instar nymph (exact age uncertain) the testes have grown considerably. Most of the follicular contents have reached the stage of the zone of spermatocytes of a mature testis. The paired follicles are fused basally and a vas deferens leaves each testis and runs posteriorly through the fat body. Each of the vasa deferentia becomes slightly narrower and eventually ends abruptly and independently. The vasa have the same structure as those of *Anisolabis littorea* (White) (Labiduridae)[4]. The genitalia also show growth and differentiation from the condition in the first instar. The organ is still flattened: it is single basally and double apically, each apical portion consisting of a mesomere and a paramere, which projects back beyond the mesomere. The basal portion, and the full length of each mesomere, is traversed by a single ejaculatory duct. Sections of the genitalia and ducts closely resemble those figured by Qadri[3]. No ducts or other structures join the base of the genitalia.

According to Ramamurthi[5] the vasa deferentia of *Euborellia annulipes* (Lucas) (Labiduridae) are present in the first instar, before the genitalia appear. He describes the ultimate fusion of the vasa with the ejaculatory ducts during the fifth and final instar. The present work confirms, to some extent, the process described by Ramamurthi.

Lhoste[6] traces the development of parts of the reproductive system of *Forficula auricularia*, in particular the unusual 'nodiform gland'[6–8] or 'ejaculatory canal'. It is apparent from Qadri's description[3] that, in *F. auricularia*, development of the gonads and genitalia is more rapid (and the two sets of organs are less independent) than in *L. r. truncata*, even after allowing for the additional nymphal instar of *L. r. truncata*. The independence of the ectodermal phallic rudiments from the mesodermal vasa deferentia in *L. r. truncata* does not accord with the

widely held view on the derivation of the tissues of the genitalia. The condition in *L. r. truncata* accords with the views of Abul-Nasr[9] concerning the origin of the tissues of the insect gonads, ducts and genitalia.

As the phallic lobes are first seen after the embryonic limb buds have disappeared, there is no evidence as to which segmental structures, if any, enter into the formation of the phallic rudiments. It is only certain that the phallic lobes are associated with the inner surface of the ninth sternum, the general arrangement in insects. Nothing, therefore, can be done at present to resolve the differences between the divergent opinions of Else[10], Roonwall[11], Snodgrass[2], Gustafson[12] and Bouthier[13].

This work is continuing and will be reported in full elsewhere. I thank Mrs. W. Walker for her help.

Chiasma Frequency and Gregarization in Locusts

Phase transformation of locusts[1,2] is the reversible group of morphological, biochemical, physiological and behavioural changes in locust hoppers or instars and adults, based to a large extent on population density. The transformation to the swarming or gregaria phase occurs in the field when individuals of the grasshopper or solitaria phase congregate in large numbers due to rapid growth of population. The brown locust, *Locustana pardalina* Walk., is at present in a cycle of intensive gregarization after a period of about seven years of mainly solitaria life. Gregarization started during the summer of 1962–63 in many areas of the approximately 100,000 square miles of the outbreak region in the Karoo plateau, and continued in the formation of swarms over most of the region during early summer of 1963–64. Many of these swarms have consequently passed through at least three generations of gregarization in the field. Through the courtesy of the Locust Control Division our Locust Research Unit has received field collections throughout the past four years so that representative samples of solitaria, congregating populations and swarms with a history of 1, 2 or 3 generations of gregarization have been available.

Cytological investigations of the brown locust have shown that the 11 autosomes of the chromosome complement of the male are very similar in relative mitotic metaphase lengths to those of other locust species[3], and assort into the general classes of three long (3*L*), five medium (5*M*) and three short (3*S*). During meiosis in the male the 3*S* chromosomes regularly pair with 1 chiasma each, but the frequency varies in the 3*L* and 5*M* chromosomes as shown in Table 1 in which mean frequencies for the two groups are given with their error variances. These populations comprise a selection of the many that have been scored for chiasmata, and the amount of gregarization in the field is the minimum estimates based on field counts of population density and the number of generations per season. The data clearly show a rise in chiasma frequency in the 8 largest chromosomes during the course of the swarming cycle. This increase is considerable and the differences between field solitaria and gregaria is of an order much greater than differences which have been found in geographical populations of grasshoppers[4], in wild populations of plants[5], in strains of *Drosophila*[6,7] or in inbred lines of rye[8].

Table 1. Mean Chiasma Frequencies in the Three Long and Five Medium Chromosomes with their Error Variances

Area in outbreak region	Population symbol	Generations of field gregarization	Chiasma frequencies in 3*L*	Chiasma frequencies in 5*M*
North	*Ma* 1	0	5·68	5·21
			0·00478	0·00149
	Ma 2	1 (medium)	6·63	5·56
			0·00494	0·00303
	Ma 3	3	7·44	6·97
			0·00275	0·00429
North central	*H* 1	0	5·79	5·11
			0·00840	0·00129
	H 6	1 (medium)	5·98	5·32
			0·00434	0·00117
	H 7	2 (1 medium)	6·23	5·40
			0·00613	0·00196
	H 8	2 (full)	6·73	6·14
			0·00574	0·00787
	H 9	3	7·17	6·62
			0·00358	0·00405
Central	*A* 1	0	5·40	5·07
			0·01231	0·00091
	A 7	2 (1 medium)	6·99	6·37
			0·00312	0·00447
	A 8	2 (full)	7·11	6·43
			0·00574	0·00563
	R 1	2+	7·48	7·26
			0·00670	0·00898
	Hn 1	3	7·56	7·06
			0·00255	0·00324

Polygenic control has been suggested for differences in chiasma frequency in a species[5–8]. The increased chiasma frequency in gregarized brown locust populations is probably also the result of such a kind of control. Miss M. D. Willemse of the Locust Control Division has provided hoppers from a selection experiment on the colour of the instars in cages with low densities of population. The P_1 of this investigation was derived from egg pods deposited in an egg nest or field by a swarm in about the second generation of gregarization. She selected two lines, the first for typical black gregaria hoppers and the second for green (solitaria-type) hoppers. The hoppers scored for chiasma frequency were the F_2 of selection and yielded the data given in Table 2.

Table 2. Mean Chiasma Frequencies in Lines selected for Instar Colour

Selected line	Chiasma frequencies in 3*L*	Chiasma frequencies in 5*M*
Gregaria hopper colour	6·45	5·71
	0·00402	0·00207
Solitaria hopper colour	5·92	5·44
	0·00329	0·00148

Solitaria females lay eggs which produce small grey hatchlings while gregaria females produce large black hatchlings. In several instances it has been found that in populations which were building-up, that is, starting to congregate, pods were deposited which hatched into either black or grey hatchlings, presumably depending on the previous history of the mother. In one such a mixed population the chiasma frequencies of Table 3 were scored.

Table 3. Mean Chiasma Frequencies in Sub-strains from a Congregating Population

Sub-strain	Chiasma frequencies in 3*L*	Chiasma frequencies in 5*M*
From black hatchlings	6·94	6·34
	0·00540	0·00509
From grey hatchlings	5·87	5·38
	0·00407	0·00224

The rise in chiasma frequency in gregarizing populations of the brown locust indicates a large increase in genetic recombination, but whether this increase is initiated before or is a correlated characteristic of swarming is not quite clear from the present data. Increased recombination through the breaking up of linked congeries of genes may be of great importance in populations due to

changes in selective values of particular sets of genes[9], especially in the case of the locust migrating into an invasion territory with ecological conditions quite different from those of its natural habitat. The first indications in the laboratory breeding of F_1 from field collections are that increases in chiasma frequency are transmitted to offspring, irrespective of the density of populations in the cages.

Genetically Controlled Variation in Pteridine Content of *Pieris brassicae* L.

IN various insects, simple recessive mutants which have a distinctly different pteridine content from the wild type have long been recognized[1]. This phenomenon has been particularly well investigated for the eye-pteridines of the imago of *Drosophila melanogaster*. In all these cases, the presence or concentration of one or more of the 6-substituted pteridines and/or isoxanthopterin is affected. For Pieridae, a family in which pteridines occur in great variety and large quantities, no such mutants have been described. Sexual differences in pteridine content or composition can be very marked in some species of Pieridae, for example, in *Euchloe cardamines*. Also some geographical races of *Pieris brassicae*, for example, race *cheiranthi* (Hübner) of the Canary Islands, are, because of differences in pigmentation, suspected of having a different pteridine composition.

Recently, Gardiner described two genetically controlled colour-variations of *Pieris brassicae* which appeared as mutations in a laboratory colony: *ab. coerulea* and *ab. jauni*[2]. Both these mutants differ from the wild type in the amount of yellow pigmentation: *ab. coerulea* lacks all yellow, and shows a slight blue iridescence; *ab. jauni* shows a marked increase in yellow pigmentation, especially on the underside of the hind wings. Since the yellow pigmentation of the wing scales of the wild type depends on small amounts of xanthopterin and erythropterin mixed with the much larger quantities of colourless substances, that is, leucopterin, isoxanthopterin and uric acid, it was suspected that the mutants were affected in their pteridine composition.

Wing extracts were chromatographed on paper, and the resulting chromatograms showed a marked difference in pteridine composition when viewed in ultra-violet light. Xanthopterin and erythropterin are completely lacking in *ab. coerulea*, while both these substances, especially erythropterin, are present in increased amounts in *ab. jauni*. Another colour variation in *Pieris brassicae*, *ab. albinensis*[3], does not differ from the wild type in pteridine. composition. The change of colour in this mutant depends entirely on an incomplete melanin formation.

The main point of interest here is that in *Drosophila* the genetic variation in pteridine composition in all described mutants involves the 6-substituted pteridines and isoxanthopterin; while in both *ab. coerulea* and *ab. jauni* of *Pieris brassicae*, a 7-substituted pteridine (erythropterin) and xanthopterin are involved. This linkage of isoxanthopterin to 6-substituted pteridines and of xanthopterin to a 7-substituted pteridine, whenever genetically controlled variations occur, may well be an indication of a rather strong metabolic connexion. It seems that naturally occurring isoxanthopterin is an oxidative breakdown product of the 6-substituted pteridines and that naturally occurring xanthopterin is an end-product of the oxidative breakdown of 7-substituted pteridines. The bioconversion from 7-substituted pteridines to 6-substituted pteridines, as well as the bioconversion from xanthopterin to isoxanthopterin, appear to be metabolic impossibilities.

MICROBIOLOGY

Occurrence of Nematode-trapping Fungi in the Rhizosphere

ALTHOUGH there are many species of predaceous fungi that capture and kill nematodes in soil, there are little if any data in the literature to indicate if they are preferentially stimulated by roots. Since nematodes tend to accumulate in the root zone or rhizosphere[1] we determined the incidence of nematode-trapping fungi in this region as compared with root-free soil.

Wheat and soybean were grown in pots in the greenhouse for 4–6 weeks. On removal the roots were shaken to dislodge loosely adhering soil and clumps, and sections with rhizosphere soil adhering were placed on the surface of 'Difco' corn meal agar containing 30 mg chlortetracyclene/l. to suppress bacteria. Root-free soil was distributed uniformly on plates of this agar medium at the rate of 10–20 mg per plate. Root material was also washed thoroughly in tap water and then in 5 changes of sterile water and segments of approximately 0·5 cm were placed on the agar medium. Fifty plates were prepared for each sample. To each plate was added a suspension of living nematodes of the genus *Panagrellus* (kindly supplied by Dr. E. Hansen, Kaiser Foundation Research Institute, Richmond, California, U.S.A.) to stimulate trap-formation[2] as an index of the presence of the predaceous fungi. The plates were incubated at 20° C and examined thoroughly after 3 and 6 weeks.

Table 1. PERCENTAGE OF PLATES SHOWING *Arthrobotrys* IN THE ROOT ZONE OF WHEAT AND SOYBEAN. 50 PLATES IN EACH COUNT

Plant	Root segments	Rhizosphere soil	Root-free soil
Soybean	0	86	62
Wheat	0	32	

The data given in Table 1 show an interesting distribution of fungi in the zones indicated. *Arthrobotrys oligospora* Fres. was the only nematode-trapping fungus that was consistently isolated, although in a few plates there was evidence of other types producing constricting rings, and occasionally of the endozoic predator *Harposorium*. Perhaps the most striking feature was the complete absence of *Arthrobotrys* on the root segments compared to its occurrence in the soil samples. The data strongly suggest that this fungus is a soil-inhabiting organism, in the terminology of Garrett[3]. Also noteworthy is the greater abundance of the fungus in the soybean rhizosphere as compared with that of wheat. Repetition of these experiments revealed an essentially similar relationship, implying that the type of plant used exerts a strong influence on the incidence of this fungus. Recent work from our laboratory[4] showed that under certain conditions soybean rhizosphere soil contained four times as many nematodes as wheat rhizosphere, a fact that may account

for the prevalence of these fungi in the root zone of soybean.

GENETICS

Genetics of Plasmids in *Salmonella typhimurium*

In bacteria certain genetic determinants which may be gained or lost can multiply without incorporation in the bacterial chromosome. Some such plasmids[1], the class of episomes[2], may become reversibly integrated into the chromosome; for others, including the transmissible drug-resistance (*R*) factors[3], integration has not been unequivocally demonstrated. We report observations on the transmission of an *R* factor and of colicine factors by conjugation and transduction in *Salmonella typhimurium*, and show that *R* factor genetic material may become attached to the bacterial chromosome—but only by becoming associated with an episome, prophage *P22*.

The strain to be used as donor was an *LT2 Hfr* derivative[4] (received from Dr. N. D. Zinder of the Rockefeller Institute) which injects its chromosome 'clockwise' from *ile**. It was first infected with three colicine factors, *colI*, *colE*1 and *colE*2, by the high-frequency colicinogeny transfer method[5] and then by conjugation with an *R* factor (isolated in England by Datta[6]) which confers resistance to sulphonamides, streptomycin and tetracycline. The strain so obtained was mated with an *LT*2 *adeC proA ile*, etc., recipient. The relative frequency of different recombinant classes and interrupted-mating results indicated the gene order:

$$-ile-rha-mal-inl-(ara,\ azi)-pro-gal-$$

Some chromosomal recombinants—the proportion varied from 15 to 100 per cent in different classes—were found to have acquired one or more of the colicine factors of the donor; and 0·1–1 per cent had acquired the *R* factor. However, none of the plasmids showed linkage to any of the chromosomal loci which were segregating. It appears that in this mating the four plasmids are transferred unattached to any standard locus on the *Hfr* chromosome; similar results have been reported for transfer of colicine factors[7,8] and of *P*1–*dl* (an aberrant prophage[9]) during *Hfr* mating in *Escherichia coli*.

Some plasmids can be transduced. We grew phage *P22* by the lytic cycle on the *Hfr* strain carrying the three colicine factors and the *R* factor, and used it to infect the *ade pro ile* recipient at a multiplicity of *c.* 5. Sulphonamide-resistant (*sul-r*) and tetracycline-resistant (*tet-r*) transductants were obtained, at frequencies per plaque-forming unit of 10^{-8} and 10^{-9} respectively; frequencies lower than those for transduction of *ile*$^+$ (10^{-6}) and of *pro*$^+$ (10^{-7}). All *tet-r* transductants tested were sensitive to sulphonamides and streptomycin; all of *c.* 500 *sul-r* transductants tested were also *str-r*, but only two were *tet-r*. Separate transduction of the *tet-r* trait and of the other *R*-factor resistance traits has been observed before in *Salmonella*[10,11]. Some *tet-r* and some *sul-r str-r* transductants produced colicine *E*1 or colicine *E*2. This we attribute to co-transduction of the *colE*1 or *colE*2 factor with the drug-resistance determinants. In control experiments we never observed co-transduction of resistance traits or of colicinogeny with the chromosomal genes *ade*$^+$ and *pro*$^+$. The co-transduction suggests that in some donor cells a colicine determinant is closely associated with part of the *R* factor.

Nearly all the resistance-trait transductants were normally lysogenic for *P22*—as is generally the case for *P22* transductants. Most of 15 exceptional transductants not releasing phage *P22* (from a sample of about 200 transductants tested) were, however, resistant to *P22*, and we, therefore, suppose them to be defectively lysogenic; that is, to carry a *P22* prophage which is deficient, at least in function. As *Salmonella* resistance-trait transductants in general do not transmit their drug-resistance by conjugation[10,11], it has been surmised[3] that the transduced fragment of the *R* factor may be integrated into the chromosome of the recipient bacterium, perhaps at a region of genetic homology. We attempted to map the transduced resistance traits of *T*1, a defective lysogenic *tet-r* transductant, and of *T*3, a defective lysogenic *sul-r str-r* transductant. A genetically marked *LT*2 strain as donor was crossed to *T*1 and to *T*3 as recipients by the *col*-factor hybridization method[12]. In each cross more than 95 per cent of recombinants selected for possession of the *pro*$^+$ locus of the donor parent acquired also its *P22*-sensitivity and drug-sensitivity; by contrast, recombinants selected for possession of the donor *ade*$^+$ locus had the phage-resistance and drug-resistance of the recipient parent. That is, both the *P22*-resistance (defective lysogeny) and the transduced drug-resistance trait (*tet-r* in *T*1 and *sul-r str-r* in *T*3) showed very close linkage to *proA*. In normally lysogenic *LT*2 strains *P22* prophage maps close to *proA* (Sylvia Smith and Stocker, unpublished results; Zinder, personal communication). These results and others suggest that in each of these two defective lysogenic transductants the *R*-factor fragment determining drug-resistance is associated with an abnormal *P22* prophage at the usual *P22* prophage site on the chromosome. Thus, as surmised, transduced *R*-factor genes have become located on the bacterial chromosome—but only through association with an episome having an attachment site there, not by crossing-over into the chromosome at a region of homology.

The vegetative multiplication of a prophage which carries genes of non-phage origin may result in production of many abnormal phage particles, able to transduce the character concerned—for example, galactose-fermentation in the case of the abnormal prophage, λ-*dg*. We encountered evidence for such a phenomenon when we examined a *tet-r* transductant, *T*10, which we term a 'semi-defective' lysogenic. It is *P22*-resistant and, though its overnight broth cultures contain < 50 plaque-forming units/ml., normal *P22* can always be recovered by enrichment with a phage-sensitive strain. Unlike ordinary *Salmonella* resistance-trait transductants, line *T*10 grown in mixed culture transmitted *tet-r* at about the same rate (10^{-3}/donor cell) as a strain carrying the whole *R*-factor and able to conjugate. We infer that *T*10 transmits *tet-r* by *P22* transduction, not by conjugation, because: (1) even cell-free filtrates of *T*10 cultures on long incubation evoked *tet-r* clones from smooth (*P22*-sensitive) recipient strains; (2) incubation with *T*10 cultures or filtrates failed to evoke *tet-r* clones from rough recipients, which do not absorb *P22* though they readily accept *R*-factors by conjugation. *T*10 culture filtrates which transmitted *tet-r* to an *ade pro* acceptor contained < 50 plaque-forming units/ml. and did not transmit the *ade*$^+$ or *pro*$^+$ characters of *T*10; the filtrates thus have the high-frequency transduction property in respect of *tet-r* but not of other genes. The addition of *P22* phage grown on a drug-sensitive strain to a mixture of *T*10 filtrate and acceptor bacteria greatly increased the number of *tet-r* clones obtained. Thus, as in other special transduction systems, normal phage helps the abnormal particles to effect transduction. When *T*10 filtrates are incubated with *P22*-sensitive recipient bacteria a high titre of normal phage results from the

* Genotype symbols: *ile, ade, pro*, requirement for, respectively, isoleucine, adenine, or proline; *rha, mal, inl, ara, gal, lac*, fermentation of, respectively, rhamnose, maltose, inositol, arabinose, galactose or lactose; *azi*, azide resistance; *colI, colE*1, *colE*2, factors determining production of, respectively, colicines *I*, *E*1 or *E*2.

multiplication in the recipient cells of the rare normal *P22* particles in the *T10* filtrate; the need for 'helper' phage presumably explains the necessity of long incubation of the mixture before selection for *tet-r*. We infer that in transductant *T10* (as in *T1* and *T3*) the transduced *R* fragment is associated with a *P22* prophage, and is, in consequence, replicated during vegetative prophage multiplication; and that many phage particles carrying the *R* fragment, and so able to transduce *tet-r*, are thereby produced.

Transductants *T10*, *T1* and *T3* may themselves have resulted from recipient bacteria becoming lysogenic for abnormal *P22* genomes with associated *R*-factor genes, introduced by abnormal particles present in the original *P22* lysate of the *Hfr* strain carrying the *R* factor. Possibly all transduction of *R*-factor drug-resistance traits in *Salmonella* is effected by such abnormal phage particles, the normal lysogeny of most transductants resulting from superinfection by normal phage. As has been surmised[3,11] transduction of *R*-factor resistance-traits in *Salmonella* would then be an instance of the transduction by lysogenization observed[13] when the *lac*$^+$ genes of *E. coli* were transduced by phage *P1* to the inherently lactose-negative species *Shigella dysenteriae*, or to *E. coli* mutants in which the *lac* region had been deleted. With such recipients unstable *lac*$^+$ clones were obtained, in which the *lac*$^+$ genes were associated with *P1* genes in an abnormal prophage. Luria *et al.*[13] suggested that in ordinary general transduction the bacterial genes introduced by an abnormal phage particle are readily incorporated into the recipient chromosome by crossing-over at the homologous region; but that when no such region exists this is impossible and the introduced bacterial genes will not be replicated unless they come to form part of a prophage, a plasmid able to ensure its own replication. The *R* agent when transferred *in toto* by conjugation (or by *P1* transduction in *E. coli*) presumably carries genes able to ensure its own replication as a non-chromosomal particle. In *P22* transductants the drug-resistance determinants of the *R*-factor become separated from such genes; lacking homology with the bacterial chromosome, they can then, perhaps, be stabilized only by becoming associated with a *P22* genome, able to attach to the chromosome as prophage.

Recovery of Monokaryons from Veil Cells of Fruit Bodies of *Coprinus lagopus* sensu Buller

A USEFUL feature of the dikaryon of *Coprinus lagopus* sensu Buller is the ability to recover monokaryons with nuclei of one or other of the component types. It is thus possible to confirm whether the genotype of these nuclei has remained unchanged in the dikaryon during vegetative growth since the two parental monokaryons fused. It also makes possible the investigation of one nuclear type in cytoplasm derived in part from another monokaryon.

Fig. 1. Chains of cells from the veil of *Coprinus lagopus*. ×200

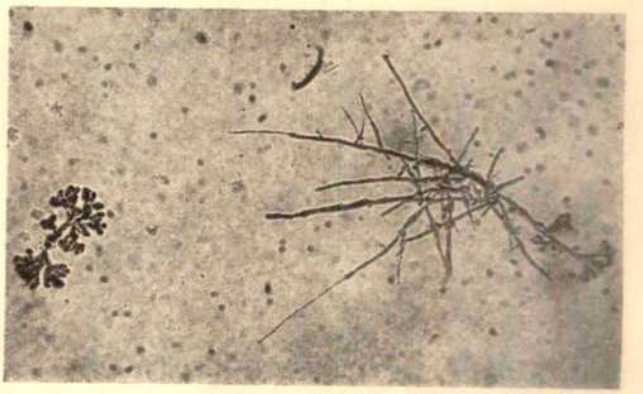

Fig. 2. Germinating veil cells of *Coprinus lagopus*. The one on the left has produced only dendroid mycelium. That on the right has produced both dendroid and normal mycelia. ×*c.* 50

The dikaryon produces chlamydospores which fall into two main classes: (*a*) round spores which germinate by one germ tube to give dikaryon and (*b*) long spores which may germinate from both ends to give monokaryon in the first instance. The hyphæ arising from long chlamydospores soon become dikaryotized, but early isolation of hyphal tips gives a reasonable proportion of monokaryons[1].

A strain of *Coprinus lagopus*, disomic for one chromosome, is under investigation and has been used as one of the parental monokaryons in the production of dikaryons and fruit bodies. Chlamydospore analysis has demonstrated the persistence of disomy in the dikaryon, but the extra chromosome was sometimes lost before the production of basidiospores. It was therefore desirable in subsequent crosses to know whether the disomy had persisted in the fruit body before undertaking an analysis of basidiospores.

Young fruit bodies are covered with a loose veil composed of chains of large cylindrical cells[2] (Fig. 1). I have found that some of these cells are viable and will germinate on agar to produce monokaryotic growth. Veil cells from young fruit bodies are in general more viable than those from mature ones.

A little of the veil from the pileus is placed in sterile water and macerated to break the chains of cells. This is done in a test-tube, used as a mortar, with a glass pestle ground to fit exactly inside the test-tube. The suspension of cells is then sown on complete medium[1] and incubated for about 18 h at 37° C. The cells may germinate from one or both ends to produce monokaryotic or dikaryotic hyphæ. By isolating monokaryotic hyphæ at this stage it is possible to recover monokaryons with the parental nuclear types.

Fig. 2 shows two germinating veil cells from the fruit body of a dikaryon between a haploid strain carrying a recessive morphological mutation 'dendroid' and a disomic strain with the wild-type allele. The dendroid gene was not on the duplicated chromosome. One veil cell has produced only dendroid growth, which must be a monokaryon with nuclei derived from the dendroid parent, and the second has produced some dendroid and some normal growth. Such normal growth has been isolated and those isolates which gave rise to monokaryon of the normal morphological type carry nuclei derived only from the disomic parent. These monokaryons have been tested and found to be disomic, demonstrating the persistence of the disomy in the fruit body. In other cases they have been found to be haploid, demonstrating the loss of the extra chromosome at some stage between the formation of the dikaryon and fruit-body production.

SOIL SCIENCE

Stability of Granular Dicalcium Phosphate Dihydrate in Soil

Bouldin and Sample[1] considered that the dissolution of dicalcium phosphate in soil was a diffusion-controlled process, and consequently the rate of dissolution would depend on the surface area of the particular sample. Since diffusion is a slow process, granules of dicalcium phosphate may remain in soil for a considerable period after application. Thus these workers observed on numerous occasions that granules of dicalcium phosphate did not dissolve completely after 3–6 months in cropped soil.

Granular dicalcium phosphate dihydrate (2–3 mm diameter) was included in an experiment at this establishment in which the influence of various periods of soil/fertilizer contact on phosphate availability was examined on five different soils. The dicalcium phosphate was mixed with each soil (2 g of granules per 4 kg of soil) 37, 26, 15 and 4 months before examination. The mixtures were stored in the open in 8-in. clay pots, buried up to their rims in sand. At each time of addition of phosphate, the soil within every pot of all treatments was thoroughly mixed. At the end of the storage period approximately 400 g of each soil/phosphate mixture was examined and any remaining white granules removed and their total weight recorded. The results expressed as percentage recovery of dicalcium phosphate are given in Table 1.

Table 1. Percentage Recovery of Granular Dicalcium Phosphate Dihydrate after Various Periods of Soil Contact*

Soil texture†	*p*H	Period of contact (months) 4	15	26	37
(1) Sand	4·7	70	40	0	0
(2) Sandy clay loam	6·5	55	10	10‡	0
(3) Calcareous loamy sand	7·1	55	20	15	0
(4) Humose clay loam	5·7	35	10	0	0
(5) Sandy clay loam	5·0	95	30	20	0

* Mean of two replicates.
† U.S. Department of Agriculture grades.
‡ One replicate only.

To check whether these granules had changed in composition during the period of contact with the soil, X-ray powder diffraction patterns were obtained (using a Nonius 'Guinier' focusing powder camera) for each sample of fertilizer residue. These showed that every sample contained pure dicalcium phosphate dihydrate; no other constituent was detected. Hence in three out of the five soils examined, undissolved dicalcium phosphate granules may remain chemically unchanged, after as much as 26 months contact with the soil.

The percentage of the added phosphate taken up by a crop of barley (phosphate uptake from the phosphate treated soil minus that from the untreated soil) grown on the soils to which the granules had just been added was 4·5, 6·2, 5·8, 3·3 and 0·3 respectively for soils Nos. 1–5. This compares well with the figures for percentage recovery after 4 months soil contact. An exception is soil 4, in which the texture and a dark colour combined to make recovery of intact granules difficult because of staining.

We thank Dr. R. V. Coates and G. Woodard for the X-ray data.

VIROLOGY

A Rich Source of Mouse Interferon

Considerably the richest source of mouse interferon, out of seven tested, has been found to be the brains of mice infected with the arbovirus West Nile (WN)[1]. The amounts of interferon present in one such brain are large enough to protect two or three other mice against a systemic infection with a large dose of an encephalitis virus[2]. The preparation of such mouse interferon and its properties are here described.

WN virus was obtained from Dr. J. S. Porterfield, Mill Hill, London. The strains of mice used[1] and the method for assaying interferon by quantitative hæmadsorption[3] have been described elsewhere. Interferon titres were standardized in terms of a reference preparation titrated in parallel[1].

Mice were infected intra-cerebrally with WN virus, and their brains were collected 3 or 4 days later. The brains were blended in Hanks's saline, using 2 ml. per brain, and the resultant extracts were twice centrifuged at 44,000*g* for 120 min to sediment virus particles. The top two-thirds of the supernatant from the second centrifugation constituted the interferon preparation.

In a typical experiment, the first centrifugation reduced the content of infective virus in the supernatant to 0·11 per cent of the initial level. The interfering activity of the re-suspended pellet was only 0·35 per cent of that of the final interferon preparation, and thus probably due to contamination with the interferon-containing supernatant. No infective virus could be detected in the final preparation, either directly or after blind passage, by inoculating

it into mice intracerebrally or into tissue cultures of mouse or hamster cells. Since the interfering activities of the final preparations were thus not due to the presence of virus, the preparations could be directly assayed for interferon. The same titres were obtained if preparations were treated at *p*H 2 for 24 h before assay, or if they were mixed with a potent rabbit antiserum to WN virus and held at room temperature for 2 h before assay.

In a growth curve experiment, *BSVS* mice were infected with 600 LD_{50} of virus. Many mice died from the fifth day onwards, and there were no survivors on the tenth day. Titres of virus and interferon in brain extracts are shown in Fig. 1. The interferon reached a peak level 78–90 h after infection, and thereafter declined slowly until the last time of sampling on the seventh day.

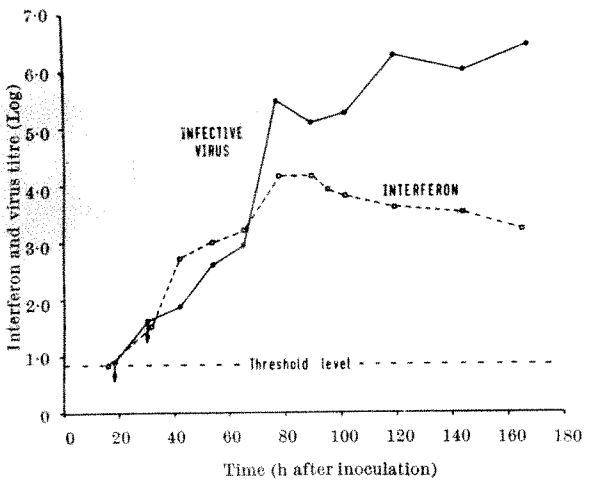

Fig. 1. Formation of infective virus and interferon in the brains of mice infected with 600 LD_{50} of West Nile virus. ●, Infective virus (log plaque-forming units/ml.); □, log interferon titre/ml.

In other experiments it was found that, over a wide range, the exact dose of virus and time of collecting had little effect on the yield of interferon in brain extracts. Mice inoculated with only 3 LD_{50} had small amounts of interferon in their brains 3 days later, but thereafter large amounts until the sixth day, whereas mice inoculated with 300 LD_{50} had large amounts on the third day, but significantly lower amounts on the sixth day after infection. No consistent differences were noted between the results with male and female mice, with mice of weights ranging from 10 to 30 gm, and with mice of the Alderley Park 1 and *BSVS* strains.

The geometric mean titre of 23 batches of such interferon was 9,500 units/ml., equivalent to 17,000 units per mouse brain, and 1,600 units/mg protein.

The interferon in the brain extracts has the typical properties described for many other interferons. Thus it was not appreciably sedimented in 2 h by a centrifugal force of 105,000*g*, and it was stable at *p*H 2. It was rapidly destroyed by incubation with 0·2 per cent trypsin, but not with 0·001 per cent crystalline ribonuclease. It had little activity unless incubated with cells for some hours before addition of challenge virus, though 35 per cent of the maximum activity was obtained after only 3 h (ref. 3). It inhibited the growth of a variety of viruses in mouse cells, for example, Semliki Forest, encephalomyocarditis, Newcastle disease, Sendai and influenza viruses, but was relatively very much less active when tested in tissue cultures of cells derived from other species, for example, chick embryo, primary calf kidney, primary hamster kidney and *BHK*21 hamster cells. Unlike some other interferons, however, it was relatively unstable on heating at 56°, 90 per cent of the activity being lost after 30 min.

The presence of interferon in the brains of mice infected with WN virus was first described by Vainio *et al.*[4], in an investigation in which yields from the brains of genetically virus-susceptible and virus-resistant mice were compared. These authors found a greater content of interferon in the brains of the susceptible mice, but made no comment on the potency of their preparations. Interferon has also been found in the brains of mice infected with other arboviruses, O'nyong-nyong virus[5], and tick-borne encephalitis virus[6]. We have found approximately 100 times less interferon in the brains of mice after infection with Semliki Forest virus than after WN virus[1].

PSYCHOLOGY

Changes in Psychological Performance associated with Changes in Total Body Water

Changes in body water have been shown to occur in mental illness. Gjessing[1] in his investigations of periodic catatonia showed biochemical changes associated with nitrogen and water balance. Crammer[2] examined a patient with a regular 6–7-day cycle of change in mood. He noted a change in body water associated with a change in body weight. Gibbons[3] has reviewed the field in relation to changes in body water. Brown *et al.*[4] have reported cases of changes of body water (extra cellular fluid) associated with changes in mood, in conditions other than periodic psychosis. Coppen and Shaw[5] published a series of cases associated with change in body water and electrolytes. The work recorded here is associated with a larger series, Kerry[6], investigating the relationship of changes of body water and mood. In all previous series the clinical changes of mood do not always correlate with the changes in total body water in either degree or direction. The aim of the work described here is to see if a more precise association could be obtained using psychological measures.

All admissions to a large mental hospital were screened to select recurrent admissions showing an obvious alteration in mood or psychomotor activity[6]. Of this series 21 patients were given the psychological measures to be described later. The measurements of total body water and the psychological assessments were always performed at the same time. Generally the first tests were performed within a few days of admission when the patient was ill. It should be pointed out that inevitably a patient is never admitted at the beginning of an illness but only after the illness has been in progress for some time. The second, or follow-up, tests were done about a week after clinical recovery. It was not possible strictly to control the patient's diet.

(1) *Total body water measurement.* This was measured by an isotope technique using tritium. A Packard Tricarb counter was used. A prepared dose of 100 μc. of tritium in 30 ml. of water was administered by mouth on a fasting stomach. Samples of urine were collected prior to administration and samples afterwards collected at 2·5, 3, 4, 5 and 6 h.

(2) *Psychological measurements.* A number of personality tests were also given to each patient on the two occasions when total body water was estimated. The tests used were as follows: (*a*) a personality inventory with four short scales measuring anxiety, dissociation, obsessionalism, emotional extraversion; (*b*) a multiple choice Rorschach measuring psychoticism; (*c*) two time estimation measures—the productive estimation of 30 sec and the verbal estimation of 30 min; (*d*) human figure drawings.

This variety of tests was included to cover a range of relatively independent characteristics affected in varying ways by different psychiatric illnesses. It was expected that a number of the measures would not show any association with total body water for two reasons. First, clinical observations associate changes in total body water with changes in mood. Secondly, some of the measures are probably not sufficiently sensitive to changes in the individual.

Table 1. Product Moment Correlation Coefficients ($N = 21$) between Changes in Figure Drawings and Changes in Total Body Water

(1) Area (in.^{2})	−0·646	$P < 0·01$
(2) Time taken (sec)	−0·578	$P < 0·01$
(3) Horizontal deviation (in.)	+0·284	N.S.
(4) Vertical deviation (in.)	+0·477	$P < 0·05$

For these reasons expectations were largely directed to the human figure drawings. These drawings were measured using the method described by Hetherington[7] and Orme[8]. A point is made on each drawing at the place which appears to be its 'centre of gravity'. Distances of this point from the horizontal and vertical median lines of the page were measured in each case. Drawings towards the left of the vertical median line were given positive signs, those towards the right, negative signs. Similarly, drawings above the horizontal median line received positive signs, those below, negative signs. To assess the size of each drawing, the area covered by it was calculated. This was done by means of a transparent grid ruled off in half-inch squares superimposed over each drawing. Previous work with this technique showed it to be a sensitive measure of depression and of recovery from depression. Depressives, compared with non-depressives, place their drawings nearer the left-hand side of the page, nearer the top of the page and cover less area. With recovery from depression these features significantly decrease. Here the time taken to draw was also recorded.

In the present series of patients, changes in test performances were correlated with changes in total body water. It was assumed that the use of such measures would be more meaningful than the use of basal rates. With the 'draw a person' technique, the sign of the changes in position and size were reversed for those seven patients considered (independently) by the psychiatrist (R. J. K.) to have been initially in an elated mood. Of the psychological tests, only the 'draw a person' technique produced significant results. As noted, this was the technique of particular interest. Of the four figure drawing measures, all are in the expected direction, three of them at a statistically significant level.

It can be seen from Table 1 that, with a patient who is initially depressed, the size of his human figure drawing will increase as his total body water decreases. Similarly, he will, as his total body water decreases, take more time over his drawing, and it will move towards the centre of the page.

An examination of the literature shows that changes in total body water during the course of a psychiatric illness do not always follow the change in mood as judged clinically. For example, patients may appear less depressed clinically, but their total body water may have either increased or decreased. These paradoxes have never been satisfactorily explained. Also the degree of change has often been disproportionate. The work presented here, using psychological measurements, was directed to examine these problems. Significant correlation coefficients between changes in total body water and changes in human figure drawings have been obtained. As previously stated, the direction of change in total body water is often paradoxical when compared with the clinical assessment of the mood change. In this sample the measurement of mood, by human figure drawing changes, parallels the changes in total body water. It appears from this finding that further investigations into biochemical changes and their association with psychological measures of mood change are worth carrying out.

We thank Dr. H. Miller and the staff of the Sheffield Medical Physics Department for advice and for carrying out the tritium estimations. We also thank our consultant colleagues for allowing us to examine patients under their care, and Dr. Z .C. Randall and Dr. M. Griffiths for their assistance. This work was supported financially by the Sheffield Regional Hospital Board.

Semantic and Acoustic Similarity in Short-term Memory

Conrad[1–3] has shown that sequences of items which are difficult to discriminate when heard in noise are also hard to remember, even though presented visually. This result can be interpreted either: (*a*) as showing that there is a very strong acoustic factor in immediate memory, or (*b*) as an example of one of many types of similarity which impair recall. Since long-term sequence learning is hindered by various types of similarity[4,5] if this latter interpretation is correct, it would support the view that long- and short-term memory are basically very similar[6].

The following experiment attempted to decide between these alternatives by comparing the influence of acoustic similarity with that of semantic similarity, a variable which has been shown to be important in the long-term learning of word sequences[4].

The material to be remembered consisted of five-word sequences presented by tape recorder at a rate of one word per sec. No word was repeated in any sequence. At the end of each sequence, subjects were allowed 20 sec to write as much as they could recall in the appropriate order.

A different group of housewives served in each of two conditions. In condition *A* 12 sequences were drawn from a vocabulary of eight acoustically similar words (mad, man, map, mat, cad, can, cap, cat), and eight from acoustically different words of approximately equal frequency of occurrence in English (bar, cow, day, few, hot, pen, pit, sup). In condition *B*, 12 sequences were drawn from a set of eight words with similar meanings (broad, great, large, wide, big, high, long, tall), and 12 from a set of eight semantically different words (hot, old, strong, foul, deep, late, thin, safe). Similar and different sequences were presented in the same random order in both conditions. The relevant sets of words were written on cards which were visible throughout the test session. To ensure that subjects were hearing the words correctly a listening test was given both before and after the memory test. This involved presenting the 16 relevant

words in random order. Subjects were instructed to copy down each word and were allowed 5 sec to do so. Two condition *A* subjects did not score perfectly on this test and were discarded, leaving 20 subjects in condition *A* and 21 in condition *B*.

Table 1. Performance as a Function of Acoustic and Semantic Similarity (Percentage Correct Sequences)

Condition	Similar vocabulary	Different vocabulary	Difference
A (acoustic)	9·6	82·1	72·5
B (semantic)	64·7	71·0	6·3

Results were scored in terms of percentage of sequences correctly recalled and are shown in Table 1.

A large effect of acoustic similarity is shown by all 20 subjects and is thus highly significant ($P < 0.001$). There is a small effect of semantic similarity, which a Wilcoxon test shows to be significant ($P < 0.05$, 2 tail). The effects of acoustic and semantic similarity were then compared by computing a difference score for each subject, based on her performance with the similar and dissimilar sequences. All 20 subjects in condition *A* showed a greater effect of similarity than any subject in condition *B*, showing that the effect of acoustic similarity was very significantly greater than that of semantic similarity ($P < 0.001$).

These results show that semantic similarity does affect short-term as well as long-term memory. Its effect, however, is only one-twelfth as great as that of acoustic similarity. The evidence therefore supports the first interpretation of Conrad's results, that there is a strong acoustic (or quasi-acoustic) element in immediate memory, rather than an explanation in terms of the general effects of similarity shown in long-term memory.

Imprinting to a Static Feature of the Home Environment

In 1951 Ramsay[1] reported observations which suggest that recognition of the home environment by precocial birds might be regarded as a form of imprinting. This view was also expressed by Thorpe[2] and implies that imprinting can occur not only to a fluctuating stimulus but also to any salient feature of the natural environment. The occurrence of attachment to a stationary object has since been demonstrated, though not beyond controversy, by Hess[3], Gray[4], and Abercrombie and James[5]. Both Hess and Gray used as stimuli a black circle and a black triangle of comparable size. Young domestic chicks were exposed to one or the other of these figures for one day, having previously been reared in visual isolation; when later tested in a choice apparatus with the figures at opposite ends they showed a clear preference, in terms of approach behaviour, for the original over the new object. Abercrombie and James tested their chicks in a runway at each end of which was a continuous light, one of them being accompanied by a stationary polythene ball which served as a 'lure'. They found that in this situation chicks eventually formed an attachment to the lure, although they required more trials for its formation than did others which had been trained with the lure accompanied by a flickering light.

In all these experiments the chicks were reared in visual isolation before being exposed to the test object when one or more days old. This technique may well have strengthened the salience of the test figure and so increased the likelihood of attachment. The present experiment attempts to demonstrate attachment to more complex stationary objects which are, from the beginning, a part of the chicks' environment. The investigation therefore represents a closer analogy with the 'natural' situation.

Chicks of a commercial breed were incubated and hatched in the laboratory and, when dry, removed to individual visual isolation pens 12 × 13 × 11 in. high. Half the 32 chicks were reared with a cardboard box suspended against one of the walls 1·5 in. clear of the floor: the remainder were reared with a foam-rubber object similarly suspended. Troughs were placed in the opposite corners, so that a chick had to move away from food and water to approach its object. After 48 h each subject was tested in a rectangular pen 26 × 28 × 10 in. high, with the two objects suspended opposite one another in the middle of the longer walls. The positions of the objects were evenly distributed over the experiment. The chick was placed under a lid in the middle of the test pen for 1 min, and then observed for not more than 5 min. If the animal did not move within that time the trial was discontinued; if it did move it was observed for a further 5 min and records were kept (*a*) of approach movements into the areas within 8 in. of each object, and (*b*) of any physical contact with either object.

The approach results are shown in Fig. 1. Of the 32 chicks tested, 6 (3 box-reared and 3 foam-reared) stayed still and were removed after the 5-min maximum latency period, and 7 moved but did not approach either object. One box-reared subject approached both objects and was scored as a half-choice for each of them in statistical analysis and in Fig. 1. The remaining 18 birds all approached the object with which they had been reared, and did not approach the other. Thus, the approaches made to original and new objects numbered 18·5 and 0·5 respectively. The binomial test shows this discrepancy to be significant at the 0·001 level. Furthermore, 16 chicks actually contacted the original object and none of them touched the new object, a difference which is equally significant. By both these criteria our subjects demonstrated a virtually exclusive preference for the object with which they had been reared.

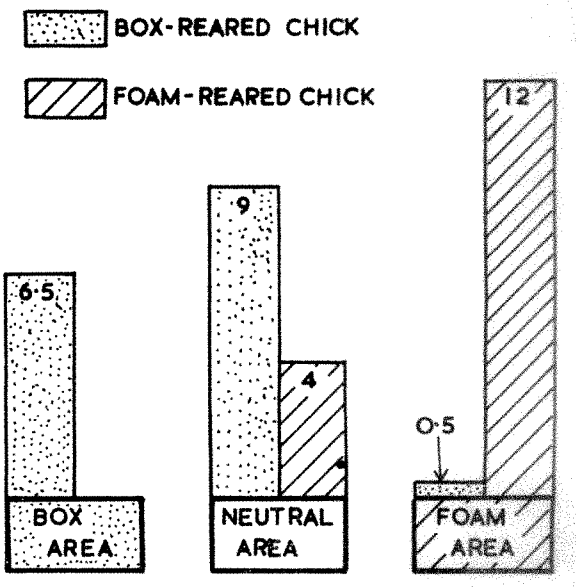

Fig. 1. Numbers of chicks entering approach areas or remaining in neutral area during test

It was observed that chicks which had been reared with the foam object often pecked at and pressed against it to the accompaniment of contentment chirps, while the others generally showed less positive activity when contacting the box. This suggested that the foam provided an intrinsically more satisfying object of attachment than the box. We tested this by comparing the proportions of the two groups which approached and which contacted their original object in the test (for this analysis the chick which approached both objects was excluded as furnishing ambiguous data). Of the 15 box-reared chicks, 6 approached the box and 4 touched it; while of 16 foam-reared chicks, 12 approached and 11 contacted the foam. The proportions test by Brown[6] shows these differences both in approach and in contact to be significant beyond the 0·05 level.

It could be argued that this result was due to chance differences in the general liveliness of the chicks, rather than to differences in the strength of attachments to the two objects, To test this we compared the mean latency times of the two groups, excluding those subjects which did not move at all. For box-reared chicks this was 2·7 min (range 0·8–4·7), for foam-reared it was 2·1 min (range 0·6–4·8). Clearly there is no significant difference between these means nor, in so far as may be inferred from latency times, in the reactivity of the two groups.

Our main result supports the hypothesis that chicks can form attachments of the kind classified as imprinting to static objects forming a part of their environment from the beginning, as well as to objects introduced into, and so disturbing, their familiar world. Although this attachment was demonstrated by our subjects in a novel situation it must have been established previously in their home environment. Nor can this be explained in terms of conventional reinforcement, since food and water were available in the corners of the pens away from the objects and temperature was constant in all areas.

It was noted, however, that the chicks appeared to seek contact with the box or the foam during the two-day period of rearing. They were often discovered sitting pressed against the object or even, in the case of the foam, actually inside it. Consequently the normally stationary objects did move when pushed, and it is possible that both contact and the movement which this produced had reinforcement value which increased the likelihood or the strength of the attachment. But chicks of this age are not particularly mobile, so that while movement of an object might occasionally have been produced by random floundering against it, systematic or frequent movement would have been unlikely unless the bird had specifically sought contact with it. Movement would therefore have been a concomitant rather than a cause of imprinting. The fact that the foam elicited stronger attachments than the box suggests that some variable akin to Harlow's 'contact comfort'[7] may have been of importance in our experiment. Further work on this question is now in progress in our laboratory[8]. We thank Prof. S. G. Lee and Dr. W. Sluckin for advice.

STATISTICS

Epidemics and Rumours

Goffman and Newill[1] have directed attention to the analogy between the spreading of an infectious disease and the dissemination of information. We have recently examined the spreading of a rumour from the point of view of mathematical epidemiology and wish to report very briefly here on work to be published in detail elsewhere[2]. In particular, we must emphasize that a mathematical model for the spreading of rumours can be constructed in a number of different ways, depending on the mechanism postulated to describe the growth and decay of the actual spreading process. In all these models the mathematical techniques familiar in mathematical epidemiology can be applied, but even the qualitative results so obtained need not necessarily be as expected on the basis of the formal analogy with epidemics.

To illustrate this point (but not to advance the model *per se*), let us divide the (finite, closed, homogeneously mixing) population into three mutually exclusive and exhaustive classes:

Class	No.	Rumour interpretation	Epidemic interpretation
X	x	Has not heard rumour	Susceptible to disease
Y	y	Actively spreading rumour	Infectious case
Z	z	No longer spreading rumour	Dead, isolated, or immune

If we assume that the only transitions are: (1) 'infections' $(x, y, z) \rightarrow (x-1, y+1, z)$, at a rate proportional to xy; (2) 'removals' $(x, y, z) \rightarrow (x, y-1, z+1)$, at a rate proportional to y; then we obtain the deterministic Kermack–McKendrick epidemic[3] in which an initial trace of infection will generate an appreciable epidemic if, and only if, the initial number $x(0)$ of susceptibles exceeds a certain 'threshold' value ρ. In this formulation the decay of spreading is due to a process of 'forgetting'. Another plausible hypothesis is that an active 'spreader' stops telling the rumour because he learns that it has lost its 'news value'; if this happens as soon as he meets another individual knowing the rumour (that is, a member of Z or another member of Y), then transitions from Y to Z occur as a result of YZ and YY encounters (with a double transition in the latter case), and hence at a rate proportional to $yz + 2[\frac{1}{2}y(y-1)] = y(y+z-1)$.

If this assumption is made, however, the behaviour of the system is strikingly different from that of a Kermack–McKendrick epidemic, and could not have been predicted from familiarity with the latter. The fraction f of the population which ultimately learns the rumour (corresponding to the fraction of the population which succumbs to the disease) is always about 0·80, almost irrespective of the value of $x(0)$, so that the familiar threshold effect has disappeared. A stochastic analysis yields very similar results; we find that f (now a random variable) has an expectation of about 0·80 and essentially a variance of approximately $0{\cdot}31/N$, where $x(0) = N$.

'Reluctance to tell stale news' can be incorporated into the model in other ways, some of which we have investigated by similar methods, and the results are then correspondingly modified. However, the object of this communication is not to urge the appropriateness of any one model of rumour-telling; but to stress the danger of transferring formulæ designed for epidemiological use without a thorough re-examination of the hypotheses, which may not always be appropriate in the new situation.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, December 14

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Du Cane Road, London, W.12), at 4 p.m.—Lord Cohen of Birkenhead: "The Lipidoses".*

SOCIETY OF CHEMICAL INDUSTRY, PESTICIDES GROUP (at 14 Belgrave Square, London, S.W.1), at 5.30 p.m.—Mr. J. G. Attfield and Mr. D. A. Wheeler: "Vapona Insecticide".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.15 p.m.—Prof. E. H. Thompson, O.B.E.: "An Itinerant Scientist in China".

Tuesday, December 15

UNIVERSITY OF LONDON (at the Institute of Obstetrics and Gynæcology, Hammersmith Hospital, Du Cane Road, London, W.12), at 2 p.m.—Mr. C. J. Dewhurst: "The Uncertainty of Sex".

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. A. V. Johnston: "Some Economic and Engineering Aspects of the Construction of New Railway Lines in Northern Canada".

INSTITUTION OF ELECTRICAL ENGINEERS, SCIENCE AND GENERAL DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Transistors—The First Encounter", opened by Mr. V. H. Attree.

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 11, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Teaching of Science in Schools, with particular regard to the Future Application of Science" initiated by Sir Graham Savage, C.B., and Mr. William G. Rhodes.

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. J. Rossiter: "Biosynthesis of Phospholipids".*

INSTITUTION OF MECHANICAL ENGINEERS, RAILWAY ENGINEERING GROUP (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "Transport to the London Airports, Present and Future".

ROYAL AERONAUTICAL SOCIETY, ASTRONAUTICS AND GUIDED FLIGHT SECTION (in conjunction with the Institute of Navigation, at 4 Hamilton Place, London, W.1), at 6 p.m.—Dr. G. V. T. Matthews: "Bird Navigation".

Wednesday, December 16

INSTITUTION OF CIVIL ENGINEERS (joint meeting with the Corrosion Group of the Society of Chemical Industry, at 14 Belgrave Square, London, S.W.1), at 4.30 p.m.—Informal Discussion on "Measurement of Thickness of Sprayed Metal Coatings on Steel; Paints for Sprayed Metal Coatings; and Measurement of Thickness of Paints Applied to Steel".

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. J. R. Probert-Jones: "An Analysis of the Fluctuations in the Tropical Stratospheric Wind"; Mr. K. R. Ramanathan: "Bi-Annual Variation of Atmospheric Ozone over the Tropics"; Mr. R. C. Smith: "A Derivation of the Meridional Velocity Profile".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Mr. H. B. Berrington: "The General Election of 1964".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. H. K. Beale: "Some Economic Aspects of Extra-High-Voltage Underground Cables"; Mr. J. A. M. Gibbons, Dr. P. R. Howard and Mr. D. J. Skipper: "Gas Pressurised Lapped Polythene Dielectric for Extra-High-Voltage Power Cable Systems"; Mr. D. J. Skipper and Mr. P. I. McNeall: "Impulse Strength Measurements on Compressed Gas Insulation for Extra-High-Voltage Power Cables".

INSTITUTION OF ELECTRONIC AND RADIO ENGINEERS, JOINT I.E.R.E./I.E.E. MEDICAL ELECTRONICS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Discussion on "D.C. Defibrillation" opened by Mr. J. Spencer.

INSTITUTION OF MECHANICAL ENGINEERS (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "The Future of Household Appliance Design".

SOCIETY OF ENVIRONMENTAL ENGINEERS (in the Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Mr. B. G. Toms and Mr. G. E. Johnson: "The Laboratory Simulation of Real Vibration Environments".

SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 6 p.m.—Mr. L. Rowland: "The Control of a Warehouse by Computer".

Thursday, December 17

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 10 a.m.—Colloquium on "Modern Techniques for Microwave Circuit Synthesis".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. B. H. Neumann: "Equations Over Groups".

INSTITUTION OF CIVIL ENGINEERS, ENGINEERING MANAGEMENT GROUP (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Management Teaching Methods—Programmed Learning" introduced by Mr. C. G. Monk.

CHEMICAL SOCIETY (in the Chemistry Lecture Theatre, King's College, Strand, London, W.C.2), at 6 p.m.—Prof. W. Baker, F.R.S.: "The Widening Outlook in Aromatic Chemistry" (Pedler Lecture).

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. W. R. Oram: "Pre-Fabricated Housing".

INSTITUTION OF MECHANICAL ENGINEERS, GRADUATES' AND STUDENTS' SECTION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.30 p.m.—Mr. P. Spear: "Development of the B.R.M.".

INSTITUTION OF MECHANICAL ENGINEERS (in the Council Chamber, F.B.I., 21 Tothill Street, London, S.W.1), at 6.30 p.m.—Discussion on "A Scientific Theory of the Golf Swing".

Friday, December 18

INSTITUTE OF NAVIGATION (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Commandant L. Oudet: "Collisions and the Law".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

READER IN ENGINEERING PRODUCTION—The Secretary, Welsh College of Advanced Technology, Cathay's Park, Cardiff, quoting Ref. No. BZ 464 (December 17).

LECTURER or ASSISTANT LECTURER IN MATHEMATICS; a LECTURER or ASSISTANT LECTURER IN APPLIED MATHEMATICS; and a LECTURER or ASSISTANT LECTURER IN NUMERICAL ANALYSIS in St. Salvator's College—The Secretary, The University, College Gate, St. Andrews, Fife, Scotland (December 19).

SENIOR LECTURER (with a good honours degree in botany, and preferably some teaching and research experience) IN BOTANY to teach students to the B.Sc. General Degree (London)—The Principal, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17 (December 19).

LECTURER (Grade II) IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar and Secretary, The University, Bristol (December 21).

SENIOR CHAIR OF MATHEMATICS—The Secretary, The University, Aberdeen (December 26).

ASSISTANT LECTURER or LECTURER IN PSYCHOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (December 31).

ASSISTANT LECTURER or LECTURER (preferably with a special research interest in physical organic chemistry) IN CHEMISTRY—The Registrar, The University, Sheffield (December 31).

ASSISTANT LECTURER or LECTURER (with a veterinary or agricultural degree) IN ANIMAL HUSBANDRY IN THE SUB-DEPARTMENT OF ANIMAL HUSBANDRY, Faculty of Veterinary Science—The Registrar, The University, Liverpool, quoting Ref. CV/364/N (December 31).

FIELD ARCHAEOLOGIST to organize and control excavations in Roman sites in the City of Leicester—The Director, Museum and Art Gallery, New Walk, Leicester (December 31).

LECTURERS or ASSISTANT LECTURERS (with interests in organic chemistry, inorganic chemistry, theoretical chemistry or high resolution spectroscopy) IN CHEMISTRY—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 05G (December 31).

MASTER TO TEACH GEOGRAPHY—The Headmaster, Leeds Grammar School, Leeds (December 31).

PROFESSOR OF CONTROL ENGINEERING—The Registrar, Ref. 59Y/E, Bradford Institute of Technology, Bradford, 7 (December 31).

PROFESSOR OF SOLID STATE PHYSICS—The Registrar, Ref. 58Y/E, Bradford Institute of Technology, Bradford, 7 (December 31).

SECOND CHAIR OF ELECTRONIC SCIENCE IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (December 31).

SENIOR LECTURER (with qualifications required to teach mathematics for honours degree courses) IN MATHEMATICS—The Registrar, Ref. 64Y/E, Bradford Institute of Technology, Bradford, 7 (December 31).

BIOCHEMIST (with a Ph.D. degree in biochemistry or chemistry and experience in modern methods of protein separation) for work on the purification of proteins which influence the behaviour of animal cells *in vitro*—Dr. C. A. Vernon, Department of Chemistry, University College, Gower Street, London, W.C.1 (January 1).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF PURE MATHEMATICS—The Registrar, University College of North Wales, Bangor, North Wales (January 1).

LECTURER IN THE DEPARTMENT OF SOCIOLOGY—The Secretary, The University, Aberdeen (January 4).

SENIOR LECTURER (with a special interest in vertebrate zoology) IN THE DEPARTMENT OF ZOOLOGY—The Registrar, The University, Sheffield (January 6).

LECTURER or ASSISTANT LECTURER IN EDUCATION at the University of Basutoland, Bechuanaland Protectorate and Swaziland—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 8).

LECTURER or ASSISTANT LECTURER IN MATHEMATICAL STATISTICS—The Registrar, The University, Manchester, 13 (January 9).

LECTURER (preferably with experience in physical electronics or materials science) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING, University of Western Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 9).

TECHNICIAN (with experience in electron microscopy) for full-time work in the electron microscopy section—The Secretary, Institute for Research on Animal Diseases, Compton, near Newbury, Berkshire (January 14).

LECTURER IN BACTERIOLOGY AT THE UNIVERSITY OF SYDNEY, AUSTRALIA—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 15).

LECTURER (with a higher degree in zoology and evidence of competence and interest in research, and experience in university teaching) IN ZOOLOGY AT THE UNIVERSITY OF QUEENSLAND, AUSTRALIA—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, January 15).

POSTDOCTORATE FELLOW IN PHYSICS IN ANY OF THE FOLLOWING RESEARCH FIELDS—NUCLEAR PHYSICS, SOLID STATE PHYSICS, MICROWAVE SPECTROSCOPY, AND THEORETICAL PHYSICS—Head of the Department of Physics, Queen's University, Kingston, Ontario, Canada (January 15).

READER IN EXPERIMENTAL PHYSICS AT QUEEN MARY COLLEGE—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 15).

LECTURER (with a good honours degree in geography, and preferably previous university teaching experience and a higher degree) IN GEOGRAPHY AT NEWCASTLE UNIVERSITY COLLEGE, THE UNIVERSITY OF N.S.W.,

AUSTRALIA—The Warden, Newcastle University College, Tighe's Hill, New South Wales, Australia; and The Agent General for New South Wales, 56–57 Strand, London, W.C.2 (January 16).

LECTURER (with research experience in the field of the physiology of marine animals) IN ZOOLOGY—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (January 18).

READER, and LECTURERS (3) IN THE DEPARTMENT OF MECHANICAL ENGINEERING, Ahmadu Bello University, Northern Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 18).

SENIOR LECTURER (with a good honours degree in geography and also a higher degree or actively engaged in research leading to a higher degree, and preferably some lecturing experience) IN GEOGRAPHY at the University College of Townsville, University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, January 29).

LECTURER (Grade II) IN THE DEPARTMENT OF INORGANIC CHEMISTRY—The Registrar, University of Bristol, Senate House, Bristol, 2 (February 14).

ANIMAL HUSBANDRY OFFICER (national of the United Kingdom or the Republic of Ireland, with a degree in agriculture and extensive experience in practical animal husbandry) IN SARAWAK, to develop the livestock industry dealing mainly with pig feeding trials and management—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/155/06.

ASSISTANT PROFESSOR OR ASSOCIATE PROFESSOR IN THE DEPARTMENT OF PHYSIOLOGY—Prof. M. Beznak, University of Ottawa, Ottawa, Canada.

BIOLOGIST, SCIENTIFIC OFFICER OR SENIOR SCIENTIFIC OFFICER GRADE (with a first- or good second-class honours degree in genetics, botany or zoology) IN THE ISOTOPE RESEARCH DIVISION, Wantage Research Laboratory, A.E.R.E., to undertake a programme of research on the effects of radiation at the cellular level—The Personnel Department (A 5089/34), Atomic Energy Research Establishment, Harwell, Didcot, Berkshire.

CHIEF TECHNICIAN TO TAKE CHARGE OF THE MEDICAL ELECTRONIC WORKSHOP—The House Governor, The Hospital for Sick Children, Great Ormond Street, London, W.C.1.

D.S.I.R. RESEARCH ASSISTANT (honours graduate in chemical engineering, physics or general science) IN THE DEPARTMENT OF CHEMICAL ENGINEERING, for work on the evaluation and comparison of methods of particle size analysis—Mr. J. C. Williams, Department of Chemical Engineering, Ref. 65Y/E, Bradford Institute of Technology, Bradford, 7.

LECTURER IN MATHEMATICS—The Principal, Bede College, Durham.

LECTURER (with a good honours degree or Diploma in Technology and some research experience) IN THE DEPARTMENT OF APPLIED PHYSICS—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1, quoting Ref. AP/N.

LECTURER (with special interests in nuclear structure problems) IN THEORETICAL NUCLEAR PHYSICS—The Secretary, Battersea College of Technology, London, S.W.11.

MASTER TO TEACH CHEMISTRY TO "A" LEVEL AND SOME ELEMENTARY BIOLOGY—The Head Master, St. John's School, Leatherhead, Surrey.

MASTER TO TEACH MATHEMATICS TO SCHOLARSHIP LEVEL—The Headmaster, Malvern College, Worcestershire.

PRINCIPAL (with high academic qualifications, a wide experience of further education, and preferably some industrial experience) OF THE NORTH STAFFORDSHIRE COLLEGE OF TECHNOLOGY—The Clerk to the Governors, North Staffordshire College of Technology, Education Department, P.O. Box No. 23, Town Hall, Hanley, Stoke-on-Trent.

RESEARCH ASSISTANT (with an honours degree in physics) IN THE PHYSICS DEPARTMENT to examine the process of ruling the lines of a diffraction grating—The Assistant Bursar (Personnel), The University, Reading.

RESEARCH STUDENT IN INORGANIC CHEMISTRY FOR RESEARCH ON GERMANIUM CHEMISTRY UNDER THE DIRECTION OF DR. K. M. MACKAY—Prof. C. C. Addison, Department of Chemistry, The University, Nottingham.

SENIOR TECHNICIAN (preferably with experience of experimental biology or physiology) IN THE DEPARTMENT OF PHARMACOLOGY, mainly for the supervision of practical classes and maintenance of apparatus—The Professor of Pharmacology, Institute of Preventive Medicine, Welsh National School of Medicine, The Parade, Cardiff.

BRITISH AID TO DEVELOPING COUNTRIES

THE surveys of the Department of Technical Co-operation by the Estimates Committee* and by the Overseas Development Institute† are of major interest from the scientific point of view because of the account given of the support of overseas research. However, that was only one aspect covered in the surveys, and, so far as the report of the Estimates Committee is concerned, it was a comparatively minor function. The Committee was much more concerned with the organization of the Department generally, with the financial control exercised over technical assistance, and with the Overseas Service Aid Scheme. It was also disturbed by education co-operation and particularly the possibility of an overlap with the work of the British Council—Britain's other main source of educational assistance (excluding capital) to the developing countries. A principal recommendation is that the Department and the Council should agree to the drawing up of a comprehensive statement to establish a demarcation of their respective responsibilities.

The Estimates Committee did not discover any duplication in services provided for students or trainees. It was considered that if the present policy were maintained by which there were two distinct bodies working in similar fields, the report of the joint working party, set up in March 1964, should provide a basis for a workable definition of areas of operation in the supply of school teachers. There is nothing in the report to refute the idea that an unofficial body enjoys certain advantages over an official body. Indeed, the Estimates Committee is convinced that Britain would have gone further in supplying educational assistance to the developing countries and would have had a better programme if the British Council had, in the past, been induced to enter into the field of supplying teachers to colonies on the verge of independence, and if it had been granted the necessary financial resources.

The Estimates Committee stresses the importance of solving the problems associated with fitting the activities of the Department of Technical Co-operation into the general pattern of overseas aid. It recognizes that it is not always easy to define the boundaries between the responsibilities of the Department and other forms of aid. Generally it approves of the Overseas Service Aid Scheme as an effective instrument. On organization the Committee recommends the appointment of a Deputy Director-General, accompanied by a review of senior posts, with the view of returning to the three-division system of administration; however, it is recognized that geographical as well as functional departments are needed. The Finance Department should be reconstituted without responsibility for any geographical area, but with responsibility for forward planning and, together with the Treasury, the Department of Technical Co-operation should re-examine the present organization for recruitment with the view of establishing one department with this responsibility. The Establishment Department should examine regularly all the other departments of the organization and, together with the Finance Department, should be made directly responsible to the Director-General or to a Deputy Director-General. The Committee also recommends a survey by Embassies and High Commissions in all countries where the Department's function is to ascertain whether technical assistance at present justifies a rearrangement of duties to allow one member of the staff to be employed full-time on technical assistance work. Any such full-time post should normally be seconded from the Department of Technical Co-operation. The Department should re-examine the work of its Middle East Development Division to see whether the needs of developing countries for technical assistance could not be served better and more economically by advisers from the Department based on London.

The criticism from the Overseas Development Institute is directed not so much at the Department of Technical Co-operation as at the pattern of British technical assistance generally: this was established at the end of the Second World War and is not wholly appropriate for present needs. Some of the institutions and expertise built up in colonial days are not fully geared to meet the new situation, partly because of a failure, particularly during the later 1950's, to build up Britain's reserves of expertise on development problems. The old colonial career services were allowed to run down in numbers, and organizations like the Directorate of Overseas (Geodetic and Topographic) Surveys and the Tropical Products Institute were subjected to years of uncertainty and frustration instead of expansion. As a result, we now face considerable manpower problems. The advisers of the Department of Technical Co-operation are mostly more than fifty, while the Department's administrators are mostly more than forty-five. Many of Britain's technical assistance personnel with any length of experience overseas are nearing retirement.

The suggestions made by the Overseas Development Institute for identifying the needs in technical assistance, for organizing Britain's resources and for improving recruitment, including the organization of a career service, were noted in an earlier article (*Nature*, 204, 715; 1964) discussing overseas research, with the exception of one point. The recent growth in the volunteer movement is regarded as the brightest spot in Britain's whole effort to help developing countries with personnel. However, under the present constitution, the value of this movement's contribution lies as much in the experience gained by the volunteers and the leavening effect on attitudes in Britain towards developing countries as in any significant increase in the skills being made available. So long as volunteers are virtually untrained and stay for such short times, their value will not realize its true potential.

The survey suggests that the voluntary societies and the Government should seriously consider whether the

* Tenth Report from the Estimates Committee together with part of the Minutes of the Evidence taken before Sub-Committee F and appendixes. Session 1963–64. Department of Technical Co-operation. Pp. xxix+243. (London: H.M. Stationery Office, 1964.) 16*s.* 6*d.*

† The Overseas Development Institute. British Aid—4: Technical Assistance. Pp. 196. (London: The Overseas Development Institute, 1964.) 7*s.* 6*d.*

next step after the expansion already announced for 1965 should be to lengthen the period of service to two years or more. This might make it worth while to give the volunteers a longer training and orientation period before leaving Britain. The further suggestion is made that enthusiasm of volunteers and other young people might be directed into more permanent institutional forms, for example, by encouraging the returned volunteer to join a properly constituted service of British technical assistance personnel, or recruiting young people under thirty-five as 'associate experts' for the United Nations in the same way as the Dutch and Germans have been doing. Longer contracts or a career service structure would also make it worth while for the Department of Technical Co-operation to arrange special training, particularly for younger recruits, and to extend the range of studentships it offers for such training. Greater provision for training relevant to overseas conditions, coupled with attachment to senior experienced workers in the field of a counselling service for sixth forms and first-year students on opportunities overseas, should facilitate rapid expansion of opportunities.

Although it was announced at the time of forming Mr. Harold Wilson's Government that a new Ministry of Overseas Development would assume the functions of the Department of Technical Co-operation, it was not until November 10 that the Minister, Mrs. Barbara Castle, was able to make a full statement on the scope of the new Ministry. The Ministry's responsibility for carrying out the Government's policies for development overseas would include the Aid Programme as a whole: its distribution between bilateral and multilateral aid and between capital aid and technical assistance; the terms and conditions of capital aid and the principles on which technical assistance is granted; the size and nature of the aid programme for each country; the management of capital aid and technical assistance; relations with international aid organizations; Britain's interest in the United Nations' programmes of technical assistance; and liaison with voluntary bodies operating in the same fields. In reply to questions, Mrs. Castle said that the voluntary bodies would include not only Oxfam but also such bodies as Voluntary Service Overseas, and that the scientific work overseas formerly undertaken by the Overseas Research Council would also be a part of the technical assistance for which the Ministry would be responsible.

In dealing with all these matters the Ministry would work in harmony with the policies of the Overseas Departments and other Departments concerned, and the purpose of the new Ministry would be to promote the progress of the developing countries, bearing in mind Britain's special ties with Commonwealth countries. The Ministry would be responsible for the Commonwealth Development Corporation and would have general responsibility for co-ordinating British policy in respect of the aid and development work of the United Nations and its Specialized Agencies and for aid questions arising from the United Nations Conference on Trade and Development. It would also assume the prime responsibility for relations with the United Nations Educational, Scientific and Cultural Organization and the Food and Agriculture Organization from the Department of Education and Science and the Ministry of Agriculture, Fisheries and Food, respectively. The Treasury would continue to deal with the International Bank for Reconstruction and Development, in close consultation with the new Ministry.

Mrs. Castle added that the whole aim in establishing the Ministry had been to create a body to bring to an end the proliferation of responsibility for matters of aid. The whole tenor of her statement and her replies to questions arising out of it shows that the changes should meet much of the criticism which the Overseas Development Institute has advanced in a series of constructive reports. She also indicated that contact on aid matters would be maintained with the Organization for Economic Co-operation and Development. Apart from a specific question about the Colonial Office and Commonwealth Relations Department arising out of the Plowden Report on overseas services (*Nature*, **203**, 439; 1964), the statement largely answered the enquiries voiced by Mr. N. Fisher in a speech on November 6 in the debate on the Address to the Throne.

Mrs. Castle should be assured of the firm support of all who appreciate the critical importance of this question of aid to the developing countries. Wisely she declined to commit the Government, at this stage, to any specific increase in Britain's contribution; however, her recognition of the great challenge which the situation presents warrants the hope that the Minister will bring a fresh and constructive mind to bear not only on the question of finance but also on the numerous other aspects on which authoritative and informed criticism has been advanced in recent months.

Pp. lxxii+1251. (Stuttgart: Georg Thieme Verlag, 1963.) 272 D.M.

BAND XII/1. In the period 1848–64 Prof. W. von Hofmann, working in the Royal College of Chemistry, carried out some extraordinarily able researches on the organic derivatives of phosphorus. The subject was afterwards comparatively neglected for very many years, being largely replaced by a much wider interest in similar arsenic derivatives. Interest in organo-phosphorus compounds began to quicken again some 25–30 years ago, and has since developed at a rapidly increasing rate; a very considerable volume of knowledge is now scattered in the chemical literature. Workers in this subject were greatly helped in 1950 by Kosalopoff's book, in which

synthetic methods were classified and described. The importance of the subject—both theoretical and technical—clearly warranted a much fuller and more modern treatment, and this is most excellently provided by Band XII/1 of the new edition of "Houben-Weyl". This volume is devoted (as the main title of the series implies) to synthetic methods, and the chemical properties of the final products are only briefly indicated. The systematic classification of the various methods for the preparation of each class of phosphorus compound, including specific experimental detail to illustrate typical preparations, occasional tables of melting-points and yields, and very full references, has been carried out with remarkable thoroughness: indeed, it would be very difficult to find any relevant matter in chemical literature which has escaped the authors. Moreover, the presentation of all this information is so attractive that the reader can with equal pleasure either 'browse' through the volume or concentrate his attention on any specific subject. The book will delight all organo-phosphorus chemists.

Band VI/2. This volume will ultimately be the second of three Parts devoted to organic derivatives of oxygen. Its contents are unusual, for the greater part (503 pp.) deals with compounds on the border-line of inorganic chemistry. Thus there are separate chapters on metal-alcoholates, -phenolates, -enolates and -chelates, on organic derivatives of silicic acid, of boric acid, and of the inorganic acids of phosphorus, arsenic, antimony and sulphur, and on the esters of nitrous and nitric acid, of the hypohalogenous acids and of perchloric acid. I am myself unaware of any other single volume in which all the foregoing subjects are discussed in such detail, and they make absorbing reading, partly because they are so far removed from the common well-worn tracks of most organic chemical texts.

The remainder (342 pp.) is devoted to two chapters, on β-lactones and other lactones respectively. The syntheses of lactones having rings of various sizes are carefully classified and described in great detail. The total information on lactones is so considerable that these two chapters, if published together, would alone make a valuable volume. This Part 2, therefore, will appeal strongly to the orthodox organic chemist and to the organic chemist having rather wider interests.

Band XIV/2. The earlier Band XIV/1 dealt in considerable detail with the nomenclature and terminology of macromolecular substances, with their preparation by the polymerization of vinyl and divinyl compounds in solution and in heterogenous systems, and with special polymerization processes for the more important monomers. Band XIV/2, a volume as massive as Part 1, is divided into three main sections. Section A, the largest of the three, deals with the preparation of macromolecular products by 'poly-condensation' and 'poly-addition', including the use of comparatively simple heterocyclic units such as substituted epoxides and ethyleneimines. This section has, therefore, a wide range: it discusses the condensation of, for example, carboxylic acid esters, organic carbonates, urethanes and amides, and that of carbonyl and thiocarbonyl compounds with phenols, amines and various other types of nitrogen compounds such as ureas, melamine and urethanes. It consequently contains detailed information on many processes of the greatest technical and theoretical value. Section B deals with the chemical properties of various types of macromolecular products and Section C with the determination of their structure. Pages 960–1069 contain a list of references (in addition to those given as footnotes in the text) classified under thirty-six subjects.

This volume, the work of many contributors, must, with Part 1, be the outstanding work on this vast subject.

The publishers and printers of the foregoing three volumes deserve warm praise for the impressive and attractive appearance, printing and binding of these works.

F. G. MANN

PHONON INTERACTIONS

Phonons and Phonon Interactions

Edited by Thor A. Bak. (Aarhüs Summer School Lectures. 1963.) Pp. xiv+640. (New York and Amsterdam: W. A. Benjamin, Inc., 1964.) 10.45 dollars.

THIS volume contains almost all the lectures given at a summer school at Aarhüs University during August 1963. The school must have been most stimulating in providing a review of all the extremely varied phenomena of the physics of condensed systems in which phonon interactions play a fundamental part.

As is inevitable in a collection of this kind, there are repetitions, and the notation is not always uniform, but these are the only adverse comments that one can make, apart from regretting that the highlights of the discussion, said to have been 'lofty', have not been included. The collection is outstanding and will be consulted with great profit by both experts and beginners. It should be particularly useful to experimentalists who wish to acquire a sound knowledge of the underlying theory. Since ample references are given, it will be used also as a work of reference.

The word 'phonon' is repeated twice in the title, as it were to stress that the relevant quantum theory is mostly expressed in terms of creation and annihilation operators. The fundamental ideas are set out very clearly in three introductory lectures, the first by H. H. Jensen on the free phonon field, the second by W. Ludwig on some aspects of phonon-phonon interaction, that is on the effects of anharmonicity, and the third by A. Sjölander on "phonons and external radiation", that is on how to obtain information on the lattice vibrations of the solid. Van Hove's space-time correlation function, which has proved so general, and which provides physical clarity, is introduced here.

In the first of the more special contributions, W. Cochran deals with the interaction of phonons with X-rays, reaching the conclusion that X-ray scattering is generally obsolete as a method of investigating the thermal spectrum. Such investigation can, however, be carried out with excellent results using neutron scattering. This is treated in detail by B. N. Brockhouse, who has himself done much to develop the method. He discusses the theoretical and experimental factors involved in the determination of the dispersion relations, frequency distributions and decay properties of the lattice vibrations. One has the impression that a complete theoretical interpretation of all the results obtained has still to be given.

J. J. Quinn discusses theoretically the phonon-electron interactions, while H. G. Reik shows how, in semiconductors, transport properties can be used to obtain information on such interactions. Additional information can be reached from a study of the absorption of long-wave phonons, and this is discussed by A. R. Mackintosh. The interaction of phonons with photons is considered by E. Burstein, who analyses in detail the infra-red, Raman and Brillouin spectra of solids arising from lattice vibrations. The theoretical treatment is particularly clear in this contribution.

The lectures by J. R. Schrieffer deal authoritatively with those aspects of the theory of superconductivity which are directly related to the phonon field and its interaction with the electrons. J. de Boer gives the theory of phonons in liquids: this problem becomes easier for liquids at the absolute zero, thus ^{3}He and ^{4}He are considered; it is shown that the excitation model proposed by Landau is very promising.

A. A. Maradudin, in a lengthy and comprehensive contribution, deals with the interaction of phonons with lattice imperfections: these lectures will be particularly useful to those wishing to become familiar with the use of Green's function methods. E. H. Jacobsen examines the generation, detection and propagation of elastic waves

in solids at frequencies higher than 10^{10} sec^{-1}. The discussion of spin-phonon interactions is especially interesting here. There is also a short contribution by K. S. Singwi on the influence of thermal motion on the Mössbauer effect, and a monograph by R. G. Kepler on the conductivity, photoconductivity and luminescence of organic molecular crystals.

In a brief summary it is inevitable that only a few points can be mentioned, but it is hoped that it has indicated how many fascinating topics are covered in these lectures and how high is the standard of treatment. Almost all the contributions are outstanding for their clarity and for bringing out the essential points, besides including the latest results. Warmest congratulations should be extended to the organizers of the school for their happy choice of topics and lecturers, to the lecturers themselves and to the careful editor, Dr. T. A. Bak, who has produced this volume in a very reasonable time with a minimum of blemishes. L. Pincherle

ALGORITHMIC DEEP BLUE SEA

The Mathematical Theory of Optimal Processes

By L. S. Pontryagin, V. G. Boltyanskii, R. V. Gamkrelidze and E. F. Mishchenko. Translated from the Russian. Pp. viii+360. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, Inc., 1962.) 90*s*.

THE calculus of variations and the science of control have developed side by side over the centuries but have only recently begun to affect one another. Norbert Wiener's classical war-time report on the filtering of noise was one of the first to introduce to control engineers some of the mathematical ideas involved in the optimization of dynamic systems. Wiener wrote in a terse and eccentric style, often using concepts belonging to nineteenth-century mathematical physics. Indeed, so incomprehensible did the bewildered engineers find the yellow-bound report that they called it "the yellow peril". Nevertheless, they discovered that it contained an algorithm which might help them to minimize the effects of random disturbances in control systems.

Now another eminent mathematician, the Russian L. S. Pontryagin, has inflicted an algorithm on the engineers. The algorithm is an extension of the calculus of variations and is called Pontryagin's maximum principle. Pontryagin and his colleagues developed their elegant and useful method in a series of masterly papers begun in 1956, and collected the results in book form in 1961. The present book is a translation from the Russian. Although prompted by engineering problems, the book is written as pure mathematics. Engineers are going to have almost as much trouble in understanding the abstract style as they had with Wiener's yellow peril. Will they call this blue-bound translation 'the deep blue sea'?

The motivation for the work stems from difficulties encountered in the application of linear theory to servo-mechanisms during the Second World War. The controlling variable (throttle opening, amplifier output, etc.) had only a limited range of variation and it was found that this saturation effect caused the performance to be worse than expected. When the saturation was taken into account the theory became non-linear. The problem was the formidable one of designing an optimum non-linear controller for the system. At first sight it seemed that the classical calculus of variations was not applicable to the problem, owing to the sharp limitations on the allowable variations in control. Nevertheless, by 1956 engineers had obtained a number of useful preliminary results, using various *ad hoc* techniques. What Pontryagin has done is to show that all these results, and many more, are encompassed by a method which virtually involves recasting the calculus of variations.

Pontryagin's maximum principle is, roughly speaking, as follows. The differential equations of the system are written in 'phase space' form, that is, as a set of first-order equations. From this a related set of differential equations, termed the adjoint system, is obtained. The maximum principle now states that, at each instant of time, the control variables must be chosen so that a certain function of the phase co-ordinates and of the adjoint variables becomes a maximum. When this is done the problem reduces to the solution of a set of ordinary differential equations of twice the order of the original system. (These differential equations have as analogues in the classical calculus of variations, the Euler-Lagrange equations when written in Hamiltonian form.)

Actually the calculus of variations had already been extended to deal with problems with inequality constraints, before the Second World War. This was done by Valentine of the Chicago school in 1937. However, Valentine's algorithm is decidedly less elegant than Pontryagin's. Also Valentine's proof depended on adding an algebraic trick to the classical calculus of variations which was already composed largely of algebraic tricks (two examples: the integration by parts in deriving the Euler–Lagrange equations, and the introduction of Lagrange multipliers). Pontryagin's method, on the other hand, potentially makes it possible to use geometric intuition and to obtain the results more 'naturally'. All the well-known necessary conditions of the classical calculus of variations follow readily from Pontryagin's results. Indeed, in the future we may well regard the classical calculus of variations as a branch of Pontryagin's theory, rather than vice-versa.

The authors, not surprisingly, have chosen to address their work to mathematicians rather than engineers, and have endeavoured to establish their theorems with utmost rigour. Unfortunately this has resulted in an extremely abstract treatment. Often a proof depends on elaborate initial constructions, the point of which does not emerge until the end of the proof, some 20–30 pages later. Little attempt is made to help the reader by preliminary heuristic outlines of arguments. Usually results are proved with maximum generality, and then simpler special cases are considered, rather than the other way round. The reader will continually find difficulty in distinguishing the wood from the trees.

For example, in Chapter 2, devoted to the proof of the maximum principle, the authors assume that the control signal is a measurable function of time. The entire proof becomes obscured with the paraphernalia of measure theory. It would have been preferable to give, at least as a preliminary, the proof for the simpler case when the control signal is assumed piece-wise continuous.

The authors also take for granted familiarity with certain mathematical concepts, especially adjoints and convexity. It would have been helpful if an exposition and perhaps a history of these concepts, in relation to the calculus of variations, had been given. If it had been pointed out that the adjoints are the differential equations satisfied by Green's functions, and that the Green's functions are the impulse responses of the linear variational system, the essence of the argument would have been simpler to grasp. Admittedly, in Chapter 1, Pontryagin and his co-authors make concessions to readability. This is an admirable survey of results, written with great care and lucidity.

The book contributes a large number of results to the theory of optimal control. Control engineers will have to make the effort to discover what these results are, even if they are unable to follow the proofs. Typical examples are as follows. The solution of Bushaw's problem when there are two control variables. The problem of attaining a given circle in the phase space in minimum time. (In connexion with problems like this one, the maximum principle yields a simple geometric interpretation of the transversality conditions of the calculus of

variations.) Optimal control of systems with time-varying parameters. Optimal control of systems with initially adjustable parameters.

One chapter deals with systems with restricted phase co-ordinates. Unfortunately the proofs are extremely elaborate, and this chapter is very unreadable. It would have been helpful if some simple examples had been given (the so-called examples given are actually extensions of the theory to related problems.) Some of the results, while of considerable academic interest, seem unlikely to be of practical use owing to the complexity of the algorithms arrived at, for example, the problem of optimal processes with a delay, and the problem of optimal pursuit of a controllable target.

The final chapter deals with a statistical optimal control problem. It is a pursuit problem, in which the pursued object is assumed to move randomly in the phase space, and only its initial position is known. The pursuer is to be controlled so that the probability of interception is maximized. The chapter is unsatisfying, because the problem itself seems unrealistic, the mathematics is extremely involved, and the final result is too complex to be used, yet is only approximate. However, as an exercise in mathematical manipulation it compels admiration.

The standard of translation is excellent. We must be grateful to the translators for their scholarly attention to detail, and to the publishers for the rapidity with which the book was brought out.

To sum up, Pontryagin's maximum principle has effected a revolution in the calculus of variations, and in the theory of control. The present book is the most complete account of the theory yet available, and is likely to become a classic. Simpler expositions will be written, but we shall often find ourselves returning to this book to discover what has or has not been proved.

A. T. FULLER

ALASKAN ARCHÆOLOGY

The Archæology of Cape Denbigh

By Prof. J. L. Giddings. Pp. xv+331+73 plates. (Providence, R.I.: Brown University Press, 1964.) 12.50 dollars.

CAPE DENBIGH is on the northern Behring Sea coast of Alaska, and at several places interesting Stone Age sites have been discovered and studied. There are two main areas where stone tools occur, namely, at Nukleet and Iyatayet, on the north-west side of the Cape. The former has yielded an Eskimo industry, and the place seemingly was occupied from the twelfth to the eighteenth century. Iyatayet is much more interesting. On top there is a level similar to that at Nukleet, but below there are two older levels, the upper of which has been called Norton and the one below it the Denbigh Flint Complex. The Norton level is not too sharply defined, as it seems to have been partially cut into by the overlying Nukleet folk, and in turn the Norton culture itself has disturbed the top of the Denbigh Flint Complex below.

The Norton people seem to be early Eskimo, and their industry includes bone and flint tools, as well as stone lamps and pottery. The latter differs somewhat from that found at Nukleet. But the level underneath is something different. The stone industry contains a number of undoubted burins of various types and there is no pottery. Indeed, in Europe one could consider it to be a late palæolithic or early mesolithic culture. At the same time, there is little or no evidence to suggest that there was any vast gap in time between the Norton level and that below. Carbon-14 dating points to a considerable antiquity, however, suggesting an age of nearly 6,000 years ago.

Are we to suggest that the Denbigh Flint Complex represents a very early pre-Eskimo stage of culture without pottery itself ultimately derived from an upper palæolithic stage of Western Europe? As the climate in Western Europe ameliorated at the close of Magdalenian times, these reindeer-loving peoples seem to have moved north following the animals. Did they penetrate into what is now northern Russia and Siberia? In Siberia early Eskimo industries have been recognized; will further investigation unearth still earlier pre-Eskimo levels? So far, there is no direct evidence for this, but little investigation has yet been made. The author of this very interesting volume has demonstrated at Cape Denbigh a succession of cultures with more or less normal Eskimo industries on top and reaching down in the lowest level to an industry which shows distinct late palæolithic affinities.

The theory that the latest palæolithic cultures of Western Europe migrated north and east following the reindeer when the climate ameliorated is not new; it was suggested many decades ago, but at that time there was no scrap of evidence to uphold it, except the fact that the culture of the Eskimo seemed not too unlike that of our Magdalenians. There are still many difficult questions to answer and the matter is by no means clear; it is to be hoped that continued investigation will throw more light on the problem and provide some satisfactory explanation of the interesting facts disclosed.

The volume is well illustrated with more than 75 full-page half-tones. A few good drawings of the implements would perhaps have helped. Prof. Giddings is to be congratulated on his work.

M. C. BURKITT

RIVER POLLUTION

Fish and River Pollution

By Dr. J. R. Erichsen-Jones. Pp. viii+203. (London: Butterworth and Co. (Publishers), Ltd., 1964.) 52*s.* 6*d.*

THIS most useful book should be read by all concerned with the well-being of our fishes and all industrialists who are, or may be, passing trade effluents into our natural waters.

Dr. Jones has reviewed very competently the research work on the toxicity to fish of a large variety of substances. There are chapters on fish and oxygen and the reactions of fish to water of low oxygen concentration. Here are described several pieces of apparatus to test these responses. It is of interest that some fish do not have an innate ability to avoid low oxygen concentrations and in fact seem to be unaware of the lack of oxygen. On the other hand, Chinook salmon (*Oncorhynchus tschawytscha*), Coho salmon (*O. kisutch*) and the large mouth bass (*Micropterus salmoides*) under experimental conditions avoided low oxygen concentrations, the degree of avoidance increasing with the reduction in oxygen concentration.

A chapter on the measurement of toxicity in the laboratory is mainly of academic interest, as these results cannot be applied without qualification in the field because most of our rivers are already polluted. If a substance is found to be toxic it should not be put into rivers until it has been exonerated by long-term field experiments.

There is a most useful chapter on the effects of lead, zinc and copper; here Dr. Jones includes many of his own excellent observations on a zinc-polluted stream in Wales. When discussing the salts of metals the author stresses "that concentration on tolerance limits must be applied with caution, for the extreme limits of toxicity, even at one specified temperature, have been determined for few substances and few fish", and that experimentally it has been shown that different fish react very differently to metallic salts at toxic concentrations.

As many salmon poachers nowadays use cyanide it is of interest to note that the threshold toxicity is as low as about 0·1 p.p.m. and that the gills of the fish dying in cyanide solutions become bright red. I agree that this is an important symptom of the cause of death, but unfortunately in a few hours the gill colour returns to normal.

Other chapters deal with organic gases, acids, alkalis, *p*H tolerance limits, synthetic detergents and soaps, complex effluents, and thermal pollution.

A discussion on the growth rates of fish in acid and alkaline waters ends with a quotation from Brown that evidence of better growth in alkaline water is circumstantial and that "no one has demonstrated unequivocally that growth rates are directly affected by the ionic composition of the water". To this I would add that most acid waters I have investigated have been overcrowded and the population thereby underfed. Given enough food, salmonids will grow well in acid waters.

The 'newer' pollutants in the form of synthetic detergents, herbicides and insecticides are dealt with adequately. The high toxicity and long life of some of the components of these substances make sad reading for anyone interested in the preservation of our fishes. It is equally distressing to learn that fish are not capable of avoiding phenol in solution at any concentration.

To the full discussion on the effect of pollution on fish eggs I would like to add that the absence or very reduced flow of water at the spot where the salmon or trout eggs are about to be laid is temporary. Once the female fish has covered her eggs with gravel the water will once again flow through the gravel. Also, the bed-making activities of the female salmon and trout are such that a great deal of the silt and detritus in the gravel is carried downstream. Consequently the gravel around the eggs is reasonably clean and will itself form an adequate filter to prevent the eggs being silted.

Dr. Jones is to be complimented on his achievement, but I wonder if the book could be made more acceptable to the less scientifically minded by the addition of simple abstracts at the beginning of each chapter. I would also like to see the generic and specific names of the fish given in the text, not as an appendix, especially as the American common names can be confusing.

J. W. Jones

TIDAL COMPUTATIONS

Tidal Computations in Rivers and Coastal Waters

By J. J. Dronkers. Pp. xii+518. (Amsterdam: North-Holland Publishing Company, 1964.) 110*s*.

"... the effect of either luminary doth likewise depend upon its declination or distance from the equator: for if the luminary were placed at the pole, it would constantly attract all parts of the waters without any intensification or remission of its action, and could cause no reciprocation of motion. And, therefore, as the luminaries decline from the equator towards either pole, they will, by degrees, lose their force; and on this account will excite lesser tides in the solsticial than in the equinoctial syzygies ..."*.

Dr. J. J. Dronkers, of the Netherlands Rijkwaterstaat, begins *Tidal Computations in Rivers and Coastal Waters* with a historical outline which may well tempt the reader to turn to the *Principia* and savour such arguments as this before following with Dr. Dronkers the development of tidal theory through the work of D. Bernoulli, Laplace, Airy and Kelvin to the present time. In his introductory outline, Dr. Dronkers states that "this book is devoted to those tidal computations in rivers and coastal waters which are of great use in the planning and construction of engineering works in tidal waters". Thus, the book is primarily addressed to engineers, and so is largely confined to shallow water phenomena: for constructional work in the oceans is not yet envisaged.

Under the term 'tidal computations' Dr. Dronkers includes the harmonic analysis of tides, and the broad range of calculations concerned with tidal propagation. Such a statement, however, gives little indication of the actual scope of the work; and a brief résumé will therefore be attempted.

Chapter 1, in addition to the historical sketch, contains reference to problems arising when civil engineering works are contemplated in tidal régimes: for example, new navigation channels, land reclamation works and tidal barrages for power or water-supply purposes. The vital 'closure' problems arising in tidal barrage works are treated more fully later in the book. In solving such problems, the engineer will nowadays make use of the hydraulic scale-model, the electrical analogue, or the mathematical model with computer. Chapter 1 contains a general comparison of these devices.

The remaining chapters of the book are distributed between four main divisions. Part 1, "The Generation and Harmonic Analysis of the Tides", occupies about one-fifth of the text. It contains sections on the necessary basic astronomy, develops the tidal potential by vector methods, and considers the inertia-less 'equilibrium tide', the constituents of which are always in advance of the real ones. There is a list of 29 tidal constituents, and a chapter devoted to practical harmonic analysis, which leads to phase and amplitude determinations for the real constituents. The work of Doodson occupies a conspicuous position.

Part 2, "Basic Hydrodynamics and Hydraulics", leads from continuity, through the Euler equations, and thence by tensor methods to the Navier–Stokes equations. There follow an introduction to concepts of turbulent motion, and the velocity-distribution arising from the mixing-length theory of Prandtl. Chapter 6 discusses both long and short waves, with the approximations appropriate to each class, and also gives some consideration to the propagation of a semi-diurnal tide on a flowing river. Chapter 7 deals with the equations for long waves in shallow water; and, in particular, with the propagation across important discontinuities in the profile, as, for example, through a gap.

In Part 3, which deals with tidal computations in rivers and coastal waters, complete chapters are devoted to each basic method of solution; that is, to the harmonic, characteristic and finite-difference methods. It occupies nearly two-fifths of the book, and presupposes in the reader a considerable mathematical background. However, in the excellent bibliography, reference is made to some basic text-books. Chapter 9, on the method of characteristics, contains some sixteen pages devoted to the fascinating question of the propagation of a tidal bore. Here, as elsewhere, the combination of physical and mathematical reasoning is impressive.

Part 4, "Practical Applications", contains condensed descriptions of the solution by the harmonic method of the problem of tides in the River Lek; and of an application of the method of characteristics to a sluice problem. The first part of the final chapter deals in outline with 'closure' problems. In the second paragraph of p. 460 the words 'ebb' and 'flood' should apparently be interchanged. The work closes with a discussion of very high tides, followed by a further short contribution on hydraulic and analogue models. Reference is made to the impressive *Delta* model at Delft, with its battery of Magnus-Coriolis cylinders.

One would expect to find this book in the libraries of all civil engineering schools and hydraulic research institutes because of its wide scope and coverage of modern analytical and computational techniques. Many readers would doubtless welcome a second (perhaps shorter) volume devoted to the detailed solution of specific problems.

R. B. Whittington

* Isaac Newton, *Principia*, Book 3, prop. XXIV (1686): Translated by A. Motte, edit. by W. Davis (1803).

The Role of Science in Civilization

By Robert Bruce Lindsay. Pp. vii+318. (New York and London: Harper and Row, 1963.) 6.50 dollars; 49*s*.

PROF. LINDSAY, who is dean of the Graduate School at Brown University, is well known for his joint contributions (with Prof. Henry Margenau) to the philosophy of physical science, notably in the book *Foundations of Physics*, now widely available in the Dover paper-back series. The present work is a sequel to these earlier books.

Although the title leads one to expect a discussion centred on the sociological and historical aspects of science, what Dean Lindsay gives us turns out to be, for the most part, a fairly straightforward summary of the philosophical positions with which his name is already associated: that is to say, a variety of the 'logical empiricism' which was transplanted in the 'thirties to the United States from Vienna, where it was inspired by the teachings of the late Ernst Mach. To this summary, Prof. Lindsay adds, first, a concise discussion of 'information-theory', in its relations to language and thermodynamics; next, a brief survey of the problems arising out of the contemporary involvement of science with public affairs; and finally, an account of the author's own 'thermodynamic' theory of ethics, which revives the attempt originally made at the turn of the century by the distinguished chemist, Wilhelm Ostwald, to define an objective moral imperative in terms of (or on the analogy of) the physical ideas of 'order' and 'negative entropy'.

Having chosen to cover so much ground, Prof. Lindsay is compelled to proceed throughout at a gallop. We are taken from subject to subject at the double, and as a result scarcely one of the hundred-odd questions put up from under our feet is pursued for more than a few pages at a time. This compression will greatly reduce the book's value for serious students of the history, philosophy and sociology of science: too often, in place of cogent and careful arguments, we have to make do with summaries or with exclamation-marks (four in two paragraphs on pp. 68–69). To elementary students, the work can be recommended chiefly for the compact account it provides of the fundamental doctrines of the logical empiricist school—particularly on the axiomatic structure of physical theories. Like others of the same school, Dean Lindsay is led by his preference for this kind of logical articulation to adopt a rather patronizing attitude towards "the scientific immaturity of biology", while his chapter on the politics of science takes us little way beyond the pre-war views of Michael Polanyi and John R. Baker about the essential autonomy of science.

STEPHEN TOULMIN

Advances in Organometallic Chemistry

Vol. 1. Edited by F. G. A. Stone and Robert West. Pp. xi+334. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1964.) 88*s*.

IT is a pity that the publishers of this book have seen fit to bring out yet another new "Advances" series. There is less justification in this case than in some others, since the type of chemistry involved could well have been fitted into the publishers' own *Advances in Inorganic and Radiochemistry*—indeed, such organometallic articles have appeared there in past issues. There are also numerous other existing review journals which could easily cope with the amount of material available.

This volume contains articles entitled "Diene-Iron Carbonyl Complexes and Related Species" (43 pages, Pettit and Emerson), "Reactions of Organotin Hydrides with Organic Compounds" (39 pages, Kuivila), "Organic Substituted *Cyclo*silanes" (48 pages, Gilman and Schwebke), "Fluorocarbon Derivatives of Metals" (74 pages, Treichel and Stone), "Conjugate Addition of Grignard Reagents to Aromatic Systems" (17 pages, Fuson), "Infra-red and Raman Spectral Studies of π Complexes formed between Metals and C_nH_n Rings" (72 pages, Fritz). The general level among these rather diverse topics appears to be quite high and the type of treatment is comparable to that in other review articles elsewhere; the last-mentioned article is perhaps the weakest in that it attempts to cover too much ground and is accordingly too discursive.

The book is well produced with adequate subject and author indexes. It will be of most use to research workers in the organometallic area, although, on account of the breadth of the field, ranging over widely different types of compounds, it may obviously not be of interest for personal libraries.

G. WILKINSON

Organic Syntheses

Collective Volume 4. Editor-in-Chief: Prof. Norman Rabjohn. A revised edition of Annual Volumes 30–39. Pp. xiv+1036. (New York and London: John Wiley and Sons, Inc., 1963.) 125*s*.

DURING the past forty-two years, organic chemists have been greatly indebted to the contributors and editors of the annual volumes of *Organic Syntheses*, in which the practical details of each synthesis were independently checked by at least two chemists; there must be exceedingly few organic research workers who have not used these volumes. The production of *Collective Volumes* every nine or ten years has been particularly valuable, because it has afforded an opportunity to incorporate any modifications in the experimental detail which later experience has shown desirable.

Collective Volume 4 is dedicated to Prof. Roger Adams, "one of the founders of Organic Syntheses, Inc., and its leader during the last forty-odd years". The book contains the usual wide spread of syntheses, which, even at this stage of development, still include the preparation of simple (but toxic) compounds such as cyanogen iodide and diazomethane. A special note is made of all compounds the preparations of which are described and which have since become commercially available. There is an increased number of warning notices of hazardous procedures or chemicals, based on information supplied by the users of the annual volumes, and indeed a printed slip has been inserted to direct attention to one dangerous operation. *Collective Volume* 4, like its predecessors, is excellent and should be in every chemical library.

F. G. MANN

Switching Theory in Space Technology

Edited by Prof. Howard Aiken and William F. Main. Pp. x+357. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1963.) 92*s*. net.

A SYMPOSIUM on "Application of Switching Theory in Space Technology" was held in California during February 27–March 1, 1962, sponsored by the American Air Force Office of Scientific Research and the Lockheed Missiles and Space Co. Twenty-five papers were presented during the course of an introductory and four working sessions; these are reprinted in full here but without recording whether there was any concomitant discussion.

About half the papers are concerned with theoretical aspects of circuit logics and switching systems, treating both analysis and synthesis of logical functions under the constraints introduced by the eventual need to turn the theory into practice. The topics include sequential digital networks, threshold logic, modular arithmetic and matrix algebra. The subject matter of papers dealing more with the practice than the theory covers engineering techniques (for example, an abrasive technique for machining ferrites), system design (for example, digital data bandwidth compressor), and switching and stor-

age devices (multi-aperture ferrites, cryogenic stores, etc.).

The quality of the papers taken as a whole is high (which perhaps is a reflexion of the fact that many of the writers are the established authorities), and all have useful bibliographies. The topics cover a wide range, from the logically mathematical to the severely practical, and it is unlikely that any one reader will be interested in them all, but this is not unusual in the *Proceedings* of symposia. In many cases the material presented is of much wider significance than the title of the book would suggest, and while the principles and techniques are undoubtedly of use in spacecraft, they could also be of considerable value in other applications where digital control and information processing are used.

G. J. Herring

Random Essays on Mathematics, Education and Computers

By John G. Kemeny. Pp. ix+163. (Englewood Cliffs, New Jersey, U.S.A., and London: Prentice-Hall, Inc., 1964.) 40*s*.

Dr. Kemeny, head of the Department of Mathematics at Dartmouth College (U.S.A.), has made many successful experiments in presenting modern mathematics to his advanced pupils. The books on *Finite Mathematics* of which he is part-author show how far he has gone in removing dead wood and in introducing and using quite difficult concepts at an early stage. In *Random Essays on Mathematics, Education and Computers* he has collected a number of his essays, all more or less grouped around his own experiences, under three headings.

In the first section Dr. Kemeny writes convincingly about mathematical values, of his efforts as a mathematical missionary, of how to encourage rigour in demonstration without stifling intuition, of why it is not undemocratic to pick out and cherish the pupil who shows himself to be mathematically gifted. These essays, like the rest of the book, are intensely human and readable, and it is difficult to resist the temptation to quote from so much wise and vivid material. Envy compels me to make one extract: in this decade, Dartmouth College Library should reach one million volumes, it takes more than one hundred mathematical periodicals, and spends more than 100 dollars a month on mathematical books; yet Dartmouth is not one of the larger colleges in the United States.

The second section deals with matters of organization, in an idiom of units and grades that will not be very familiar to the British reader, but, for example, in setting the well-rounded man against the specialist, Kemeny makes his discussion of universal interest to teachers. In the essay on "The Vanishing College Teacher", his ten points to remedy the fact that "as far as the average undergraduate is concerned, the well-qualified science professor is nearly extinct" may well be of interest to Britain's new universities. The final section considers, among other matters, the place of the computer in colleges of liberal arts and science, and the way in which computers may be expected to be of service to libraries by A.D. 2000.

This is a lively, entertaining and instructive book, which will be of value to anyone who is concerned in any way with mathematical education.

T. A. A. Broadbent

Solid Lubricants and Surfaces

By E. R. Braithwaite. Pp. viii+286. (London and New York: Pergamon Press, 1964.) 84*s*.

Since the Second World War there has been a rapid growth in the use of solid lubricants by industry, and the appearance of a text-book specifically dealing with this subject is not only welcome but also long overdue.

Research in this field embraces a number of scientific disciplines, and there is little doubt that this book will interest a wide range of readers. The author has clearly recognized this fact in compiling his manuscript, and he has devoted a number of chapters to a general introduction of friction and wear phenomena together with a survey of the many other techniques available to-day for studying surfaces. Some of this material could have been arranged with more care. One chapter, in particular, attempts to cover such diverse topics as friction and wear-testing machines, surface profilometers, X-ray and electron diffraction investigations and particle size–surface area measurements. Such close grouping requires careful attention to sub-headings, and it is confusing, for example, to be led from a consideration of surface profilometry to the question of stacking faults and other crystal defects without adequate warning.

The second half of the book provides a useful survey of the properties and uses of the many solid lubricants available to-day. The modern repertoire of the lubrication engineer is so extensive that the author has not found it possible to direct equal attention to every aspect of the field, and he has concentrated on the two most widely used materials, namely, graphite and molybdenum disulphide. The author has been particularly closely associated with the production and use of these two important lubricants, and the subject has been tackled in an authoritative manner.

The style of presentation is extremely variable, and it is to be hoped that the many clumsy passages and tiresome errors present in the text will be eradicated by the time the second edition appears. K. H. R. Wright

Location and Land Use

Toward a General Theory of Land Rent. By William Alonso. Pp. xi+204. (Cambridge, Massachusetts: Harvard University Press; London: Oxford University Press, 1964.) 44*s*.

This volume is concerned with the basic economic theory relating to the price and use of land in urban areas. It is not a book for the layman, but for all economists working in the field it is essential reading. The argument is presented mainly in mathematical terms, but Alonso goes to a good deal of trouble to make the broad sweep of his thinking clear to those who do not have a strong mathematical background, and such persons should not be put off by a quick glance at the rather formidable array of symbols and graphs which the book contains.

Alonso begins by considering the factors important in determining the demand for urban land both by enterprises and by consumers. He then proceeds to show how the forces of demand and supply will, as part of the process of clearing the market, produce a certain pattern of land use. Some of the implications of the free market solution and also some of the implications of interference with it are then considered both in a static and dynamic context.

Probably the most interesting feature of the book is the treatment of the factors determining the demand for residential land. Alonso shows in a most careful and elegant manner how the price, location and quantity of land demanded are linked together. The price of land tends to decrease as one moves away from an urban centre, but the cost of transport to such a centre goes up. Alonso shows how these two opposing influences affect the eventual demand for both quantity and location and how a consumer's expenditure on land plus transport varies in relation to his income and other expenditures. Although this is the section which is most original, the book also makes a valuable contribution to our understanding of the factors which are important in influencing the demand for urban land by traders and manufacturers, and as a whole it is a significant contribution to a difficult and somewhat neglected field. D. Walker

THE ROYAL SOCIETY

ANNIVERSARY ADDRESS*

By Sir HOWARD FLOREY, P.R.S.

AWARD OF MEDALS, 1964

Copley Medal : Prof. S. Chapman, F.R.S.

PROF. S. CHAPMAN is distinguished for his contributions to many aspects of physics, astronomy and geophysics. His work on the kinetic theory of gases now forms the basis for much detailed study of gaseous phenomena, and more than forty years ago his interest in these problems led him to consider the processes of diffusion and viscosity in stars. In addition to these important studies Chapman's name has, for more than half a century, been inseparably linked with problems in terrestrial magnetism and with a wide range of studies concerned with the high atmosphere, ionosphere and interplanetary space. From a statistical analysis of a great mass of data Chapman succeeded in demonstrating the existence of a small lunar component in the Earth's quiet magnetic field variations, and he showed that the solar and lunar diurnal variations could be separated into a predominant component originating above the Earth's surface and a subsidiary component within the Earth itself. From this he developed the general theory of the relation of the magnetic variations to the solar and lunar atmospheric tidal effects, a theory which has been fundamental to all subsequent work. After the elucidation of these quiet magnetic daily variations, Chapman began his great work on the magnetic storm effects. In a classical sequence of papers he showed how the magnetic storm variations observed on Earth could be interpreted in terms of a corpuscular stream emitted from localized regions of the Sun. This work of Chapman has stimulated a great deal of work by himself and others on the general problem of solar terrestrial relationships and particularly on the auroral phenomena. His studies have recently attained a special significance in the interpretation of the nature and consequences of the trapped radiation zones around the Earth.

Wherever one turns in geophysics or in the physics of the upper atmosphere one finds that Chapman has made fundamental contributions. For example, his theory of ionospheric layer formation is basic to the subject. He demonstrated that atomic oxygen should be dominant in the high atmosphere, and he has contributed to the theories of the ozone layer and to the problem of the night air glow. The depth and extent of Chapman's researches, which have continued undiminished for more than half a century, have brought both him and British science international renown. Indeed, his world-wide associations became of critical importance in the promulgation of the 1957–58 International Geophysical Year and he was the president of the Special Committee for the International Geophysical Year (CSAGI) from 1953 until 1959.

Rumford Medal : Prof. H. C. van de Hulst

Prof. van de Hulst is distinguished for his contributions to theoretical astrophysics. Nowadays it is unusual for a single name to be linked decisively and unambiguously with a prediction of major scientific significance, but the name of van de Hulst has this distinction. In 1944, under conditions of occupation by an enemy in which many would find scientific work impossible, van de Hulst predicted that it should be possible to observe the spectral line emitted by the interstellar clouds of neutral hydrogen in the radio wave part of the spectrum. The radiation in question arises in a transition between two closely spaced energy-levels in the hyperfine structure of the ground state of the hydrogen atom. Although, in 1944, the techniques of radio astronomy were in a rudimentary state and little was known about radio emissions from space, van de Hulst predicted that it should be possible to observe this 21-cm spectral line from the interstellar clouds of neutral hydrogen. In 1951 this line radiation was detected almost simultaneously in Holland, the United States and Australia. The episode marked the vindication of van de Hulst's predictions and immediately opened observational possibilities of great importance in astronomy. The existence of clouds of neutral hydrogen gas in the galaxy had been presumed, but no means of observing them had been available. The ability to measure the frequency displacement of the line caused by the motions of the clouds with respect to the solar system quickly led to a great clarification in our knowledge of galactic structure.

The consequences of van de Hulst's work have extended beyond the galactic system, and a great increase in our knowledge of the extragalactic nebulæ has resulted from the recent studies of the hydrogen line emission from the Magellanic Clouds, the *M*31 nebula in Andromeda and several other extragalactic systems. Further, the Zeeman splitting of the line has been measured in the gas clouds of the Milky Way and the galactic magnetic field thereby determined. Van de Hulst's prediction and subsequent work on this spectral line from neutral hydrogen have somewhat overshadowed his other contributions. He is, however, apart from this, distinguished for his theoretical work on the scattering and interaction of light and particles in the solar corona and interstellar space. Van de Hulst is a person whose great insight into physical processes has been matched by an overall integrity which has led him to a position of high esteem in the international community. In particular he was elected the first president of the Committee on Space Research (COSPAR) and he served in this capacity with distinction through many years of difficulty.

A Royal Medal : Prof. M. J. Lighthill, F.R.S.

Prof. Lighthill's earliest papers were in the field of supersonic flow, where he provided, for the first time, a rigorous theory for thin wings of finite span and for slender bodies of revolution. In later work he adopted a non-linearized theory, applying it to the effects of blast waves and the position of a detached shock wave in front of an aerofoil. Later still he initiated the aerodynamic theory of gases ionized by passage through a shock wave. In these and other problems Lighthill has shown great power in discussing the solutions of a non-linear differential equation with a singular perturbation. It was in this way that he was able to place on a firm basis the domains of analyticity of the various partial solutions which arise, and solved a number of important problems in boundary-layer flow and shock-wave theory.

Among Lighthill's most important papers are those which first gave the theory of the aerodynamic generation of sound. This has had a profound influence on the design of 'silencers' for jet exhausts. In the field of classical, that is to say, low-speed, aerodynamics Lighthill has studied the theory of jets and cavities, and developed a new method for the design of aerofoils. He has also provided a theory of the swimming of nearly spherical organisms by means of a 'squirming' motion. Prof.

* Delivered at the Royal Society on November 30.

Lighthill's interests have recently penetrated into regions of pure mathematics, where he has made significant contributions to the generalized theory of Fourier analysis. It is rare to find someone so thoroughly at home both in the applied world where engineers need guidance in the design of important apparatus, and in the pure mathematical world. His ability to bring these two worlds together shows him to be one of the outstanding mathematicians of our day.

A Royal Medal : Prof. F. W. Rogers Brambell, F.R.S.

Prof. Rogers Brambell and his research school are widely acknowledged to be the world's foremost authorities on the problems of how protein molecules enter the mammalian fœtus from the mother. The work that earned Brambell this high reputation began in the Second World War when he was trying to work out the causes of the unexpectedly high mortality of embryonic rabbits. He soon found that maternal proteins—fibrinogen and globulins—were among the normal contents of the embryonic yolk sac. How did they get there? Did they reach the embryo itself? Brambell's first major contribution was to show that the pathway of entry of maternal protein was not the placenta, as everyone had until then assumed, but the wall of the yolk sac; maternal antibodies, for example, were secreted into the uterine lumen and passed through the wall of the yolk sac into the fœtal circulation. The same turned out to be true of guinea-pigs and—before birth—mice and rats. In man and primates generally, the size and anatomical relations of the yolk sac showed it could not fulfil that function; in them the placenta might indeed be the route of entry.

The second of Brambell's major contributions to the analysis of the relations between mother and fœtus was his study of the 'selective' entry of proteins into the fœtus or infant rodent. Discrimination between one protein and another was certainly not based on mere molecular size, for γ-globulin entered more rapidly than the smaller molecules of albumin, and the fragments of γ-globulin produced by digestion with papain sometimes entered more slowly than the parent protein. 'Foreignness' had something to do with it, since in the main homologous proteins were admitted more readily than foreign proteins. Discrimination was not based on the exclusion of some proteins and the admittance of others, for proteins of all types actually entered the cells of the endodermal membrane; what happened was that some proteins passed through to the fœtal blood with their biological activity unimpaired, while others were broken down. The investigation is still in progress.

Brambell's own work and the work he has inspired in a group of distinguished colleagues and pupils have made use of the methods and ideas of experimental surgery, embryology, immunology, biochemistry and biophysics. It throws light not merely on the physiological rapport between mother and fœtus, but on every situation in which there is a selective transmission of large molecules across biological membranes.

Davy Medal : Prof. M. Calvin, For.Mem.R.S.

As a Nobel Laureate and a Foreign Member of the Royal Societies of London and Edinburgh, it is scarcely necessary to give a detailed description of the reasons for the award of the Davy Medal to Prof. Melvin Calvin, whose achievements in the fields of physical, organic and biological chemistry have won for him international recognition.

He was co-author of the first comprehensive book on the theory of structural effects and of reaction mechanism. His contribution to our knowledge of homogeneous and heterogeneous catalysis is outstanding in the extent to which he explored the border regions between organic, inorganic and physical chemistry and biochemistry, leading to the solution of problems of profound importance in biology. He initiated many enquiries, all characterized by breadth of concept and penetration of method, into the biosynthesis of peptides, nucleotides and lipids, but his name is probably best known in connexion with his work on the mechanism of photosynthesis in the higher plants, algae and the photosynthetic bacteria. These investigations have involved the development of delicate isotopic tracer techniques and are characterized by an ingenious co-ordinated use of methods derived from analytical, physical and organic chemistry demanding a profound appreciation of the underlying fundamental principles. Calvin and his colleagues have succeeded in delineating most of the processes involved in the linked assemblage of reactions by which carbon dioxide is assimilated by plants and transformed into carbohydrates and oxygen; and, in addition, by his investigations into the role of thio-octoic acid, he has linked up the photosynthetic cycle with the Krebs cycle.

Calvin's work has already had, and is continuing to have, a profound influence on the approach to both chemical and biological problems.

Darwin Medal : Prof. K. Mather, C.B.E., F.R.S.

Prof. Mather is distinguished for many original contributions to genetics, but more particularly for his study of quantitative characters and their significance in evolution and development. Prof. Mather's early work included the discovery and interpretation of interlocking chromosomes which provided important evidence for the understanding of the mechanism of crossing-over. He was one of the first to use X-rays in the study of chromosome replication and, in a different field, he made important contributions to the genetics of natural breeding systems, a subject of great interest to Darwin.

In the study of quantitative inheritance, in which the characters do not show discontinuous variation and therefore are not amenable to Mendelian analysis, Prof. Mather has developed an analytical tool whereby the components of variation, both heritable and non-heritable, may be estimated. With this method it has also been possible to detect gene interactions of the types found in Mendelian analysis. The work has led to the theory that heritable differences in quantitative characters, such as height, depend on numerous genes each with effects similar and supplementary to one another, but individually small in relation to the non-heritable variation. Using different methods of selection, important contributions to other aspects of genetics and evolution have been made. A system of disruptive selection tends to split a population into locally adapted groups and this can lead to polymorphisms such as are frequently found in many species, including man. In a different way, disruptive selection can lead to instability in development of the individual. These selection experiments have shown that both segregation of a population into discrete groups and the orderly development of an individual are under genetic control.

Prof. Mather's wide-ranging research is of special interest and value to plant and animal breeding, to genetical theory, to the understanding of the mechanism of evolution and to the control of development.

Sylvester Medal : Dr. Mary L. Cartwright, F.R.S.

Dr. Mary Cartwright is distinguished for her contributions to the theory of functions (particularly integral functions) and differential equations and topology.

After a few years of school-teaching, Dr. Cartwright returned to Oxford as a research pupil of Hardy; she also acquired and maintained an interest in the work of Titchmarsh. The intensive cultivation of the theory of integral functions stems from Riemann's famous hypothesis (1859) that a particular integral function (immediately related to the zeta function) has real zeros only. The theory, having among its founders Weierstrass, Picard and Hadamard, has attracted the efforts of the

leading analysts up to the present day, and Dr. Cartwright has earned an honoured place in the list. To break new ground in this deep and elaborate theory has needed great analytical power. A few of the headings of her work, much of which is based on results of Phragmén and Lindelöf, are: (1) zeros of integral functions; (2) maximum and minimum moduli; (3) functions of finite order in an angle; (4) directions of Borel.

Several of Dr. Cartwright's outstanding contributions, particularly those dealing with maximum and minimum moduli, have given rise to great advances by herself and others. The shadow of war deflected Dr. Cartwright's work into a different field. Early in 1938 the Department of Scientific and Industrial Research circulated a memorandum to pure mathematicians appealing for theoretical guidance in investigating solutions of non-linear differential equations encountered by physicists and engineers dealing with defence problems. Well-known equations of Appleton and van der Pol were among those which awaited a more substantial basis of pure mathematics. The appeal received a handsome response. A stream of weighty papers by Littlewood and Cartwright, jointly and individually, has continued until to-day. They show that a proper understanding of non-linear equations needs topological insight as well as powerful analysis. A powerful fixed point theorem due to Littlewood and Cartwright plays a vital part in the authors' proofs of the existence of periodic and almost periodic solutions of differential equations. At the same time, with Sir Edward Collingwood, Dr. Cartwright was making fundamental contributions to the modern theory of cluster sets.

Dr. Cartwright has proved that the administrative and social duties of the Mistress of Girton are compatible with the advancement of knowledge by profound discoveries in mathematical analysis and topology. By the depth of her discoveries as well as their extremely wide range she has established herself as one of the world's leading mathematicians and, among her sex, the leading one.

Hughes Medal : Prof. A. Salam, F.R.S.

There are very few physicists in the world who have maintained such a constant and fertile flow of brilliant ideas as Abdus Salam has achieved during the past thirteen years. His Ph.D. thesis, published in 1951, contained fundamental work in quantum electrodynamics (renormalization theory), which had already gained for him an international reputation of a very high order. On two subsequent occasions he has made contributions to the theory of elementary particles which are in the absolutely highest class.

In 1957, Salam proposed a deep and intimate connexion between the zero rest mass of the neutrino and the parity non-conserving effects in weak interactions. This theory makes a large number of very specific predictions about neutrino properties, and of the way in which parity is violated in neutrino interactions, all of which have since been confirmed by experiment. In 1961, Salam, in collaboration with J. C. Ward, proposed that the strong interactions of elementary particles should satisfy unitary symmetry. This implies that the particles and resonances should appear in super-multiplets of the same spin and parity, and well-defined isotopic properties. In particular, Salam and Ward predicted an octet of spin one mesons, playing an analogous part in strong interactions to the photon in electrodynamics. All these mesons have since been found, and the general ideas of the theory recently confirmed by the spectacular discovery of Ω^-.

These two pieces of work are both contributions to the basic laws of physics. They are not isolated achievements, but the high points in more than ten years of prolific and sustained performance. During this period Salam has published about a hundred papers and maintained his position at the fore of this rapidly advancing frontier of the fundamentals of the subject.

PRESIDENTIAL ADDRESS

Administration

A case can be made out that Council does not keep the Fellows adequately informed of what is being undertaken on their behalf within a reasonable time of its taking place, and in this connexion an enquiry is at present being made to see if practical means can be devised to overcome what at least some Fellows consider to be a shortcoming in the administration of the Society. But the lack of a regular explanatory news bulletin gives me a chance on November 30 to consider in more detail some of the activities of the Society which are somewhat baldly chronicled in the annual report of Council.

This year there are three matters I should like to direct particularly to your attention—the progress in providing new accommodation for the Society, the scope of the Fellowship, and the relationship of the Society to the organization of science.

Accommodation

Last year I gave a description of the difficulties of accommodation that have faced the Society on and off ever since its foundation, and I was able to say that most of the problems of moving from Burlington House to Carlton House Terrace were on the way to solution*.

You may remember that at this time last year a number of generous donors had undertaken to give us £361,500 towards the £500,000 that was estimated to be necessary for the suitable conversion of the interior for our purposes. I am very happy to say that the Goldsmiths' Company has now offered a very generous gift of up to £50,000 for the reconstruction of that part of the building which will contain the Council Room and the President's and other offices. We are extremely grateful to the Company for this magnificent benefaction which will bind still further the Royal Society of London to one of the great City Companies.

The social amenities have been further assured by a gift of £5,000 for what might be vulgarly called a bar, but which in fact will be a very pleasant meeting-place for the Fellows. We are indebted to Sir Ellerton Becker for this benefaction, and this gives me particular pleasure, for Sir Ellerton has already placed science in his debt by his splendid contributions to the building of the Australian Academy of Science in Canberra.

Those who are mathematically minded will calculate that we still need some £83,500 to reach our target of £500,000, and I hope that this gap can soon be closed.

During the year a building committee of Fellows has been working with Sir William Holford and his associates on plans for the alteration of the interior. These are now complete in outline, and a final examination of the condition of the interior, now that the houses are vacant, is being made. I hope that it will be possible some time next year to arrange for the plans to be exhibited to the Fellows. If all goes well building operations should start in about nine months' time, and we should be able to occupy our new apartments in eighteen months to two years after that. I hope you noted the first phrase, "if all goes well", because I have been impressed during the past year with the very many hurdles, often of a trivial character, that have to be surmounted in such an undertaking. There can be no flying leaps in this business, so that I hope that Fellows will not become impatient with the apparently slow progress that has so far been made.

Scope of the Fellowship

During the long history of the Society the composition of the fellowship has by no means been uniform or stereotyped. Indeed, we take pride in the fact that among the early Fellows were men such as Evelyn and Pepys as well as those more directly concerned with the emerging natural philosophy.

* *Nature*, **200**, 1256 (1963).

When I look out of my study window at Queen's College, Oxford, I can see a row of statues in the façade of the library. Among the kings, queens and clerics stands Joseph Williamson, our second president, who, although he was a Fellow of Queen's, could not by any stretch of the imagination have been called a scientist nor indeed even a distinguished scholar. He was in one sense a man of business and a not unsuccessful one at that. It is unnecessary now to go into the question why he, a non-scientist, was made president of a scientific society or why, by the eighteenth and early nineteenth centuries, more than half the Fellows of the Society had no scientific qualifications whatever. It is sufficient to note that in the middle of the nineteenth century the Society, adapting itself to the growing importance of scientific studies in the life of the nation and the increasing number of admirable scientists then being educated, reformed itself, so that before the end of the century it consisted of active scientists and Council contained no one who was not closely connected with the practice of science.

At the end of the nineteenth century the big decision was made to set up the British Academy, which was to be composed of Fellows engaged in activities now loosely described as arts subjects which were not then considered to be of importance or even of interest to the Fellows of the Royal Society. It was to look after disciplines not then recognized among the strictly natural sciences. This division, which is not paralleled in the structure of most foreign academies, leaves some areas in which the interests of the British Academy and the Royal Society overlap.

Fellows of our Society have for many years been elected by machinery which, though no doubt imperfect, gives scope for the Fellows at large to determine who shall join them. That this has been moderately successful is perhaps attested by the fact that Fellows who still retain a vestige of modesty are surprised and gratified when they are elected, but that with the passage of time they begin to detect signs that the scientific attainments of newly elected Fellows are not quite what they were in previous generations. This attitude of mind is by no means to be deprecated, for it is a powerful support to the determination of the fellowship not to let the standard of attainment of the Fellows decline. It is one reason why proposals for increasing the number of Fellows elected annually are closely scrutinized by the Fellows.

You might like to be reminded of the number of Fellows elected annually during the past hundred years or so. Up to and including 1847 the numbers were unlimited, but in 1848 the number of annual elections was limited to 15, in 1931 it was raised to 17, in 1938 to 20 and in 1946 to 25. This year, after many discussions, it was decided by the due processes of the Society's constitution to increase the number of annual elections from 25 to 32.

It may be as well to have on record some of the arguments that led to this decision, not only for our own purposes but for the information of the public interested in scientific matters and, in particular, in the part that the Society can play, if it wishes, in the expanding complexity of modern social organization.

It is commonly believed that present-day civilization is becoming more and more science-based and that the speed of change is greater than the human mind can comfortably cope with. What we really mean is that technology, which is based on science, is changing our lives. The study of the elucidation of the structure of the atom can perhaps be considered as a philosophical abstraction, but when technology translates the resulting discoveries into electronic gadgets our lives are profoundly, and so far on the whole agreeably, altered. Thus it is the technologist who is transforming at least the outward trappings of modern civilization, and no hard-and-fast line can or should be drawn between those who apply science, and in the process make discoveries, and those who pursue what is sometimes called basic science. The relative increase in the number of applied scientists, and the increasing importance of their discoveries, has directed the attention of many Fellows to the question whether the Society was taking sufficient note of present-day developments. In the eighteenth century the Society reflected the general lassitude of scientific performance; in the nineteenth century it adapted its components to the great increase in scientific activities characteristic of that century; and it can now be maintained that we must reflect in an adequate way the driving forces that are so rapidly changing our physical environment. These forces are to a large extent technological.

We are fortunate and privileged to have among our Fellows some of the most distinguished engineers and metallurgists in the country; all are Fellows who have made outstanding contributions to their subjects. Nevertheless, it is certain that there are many applied scientists, particularly in government and industrial environments, who if they became Fellows would greatly strengthen the Society in its relationship to the contemporary milieu. It is for the Society to devise machinery by which their originality and contributions to contemporary civilization can be assessed as against the more familiar claims of those who have hitherto formed the great majority of our potential Fellows.

We still have to work out in detail the best procedure to adopt in assessing the merits of those whose principal field of work is in technology, but I am convinced that it is by no means impossible to solve the problem to everyone's satisfaction.

We should not conceive of applied scientists as being those associated particularly with the physical sciences. Perhaps it is the biologists and those dealing with human characteristics who will have to obtain and apply new knowledge if we are to have lives which will be really satisfactory and not an unendurable succession of frustrations. Calculations have been made that if the present rate of increase of population should continue, our descendants in 600 years' time will each have one square yard of land on which to conduct their affairs. This is manifestly absurd and something is bound to happen before that time, but what? It is all too easy for both politicians and scientists to leave a problem like this alone until the position is disastrous. More than frequent loud cries and metaphorical wringing of hands is now required. Ought we as a Society to be considering how science and scientists can contribute to a solution of the great problem of bringing the human population into satisfactory, even if dynamic, equilibrium with its surroundings? Or should we wait for these matters to be tackled by people who may have little connexion with us? I have no doubt myself that we should try to lead scientific advances by positive action. Of course, we are quite accustomed to doing so in many time-honoured and valuable directions such as the mounting of expeditions to distant lands, or participating in international 'years' or 'programmes', but is it wise for the Society at this time not to have among its Fellows those skilled in demographic work or social anthropology, or even a substantial representation of psychology and psychiatry? The investigation and understanding of the psychology and even the psychiatry of rapidly expanding populations may well be of paramount importance in the near future.

The Society has not in the past been irrevocably determined not to have anthropologists among the Fellows—one can mention *Golden Bough* Frazer—nor has it been implacably against psychiatry, for Freud was a Foreign Member. However, if the standard applied in these instances were used for judging Fellows in the more usual subjects we could safely diminish the number of annual elections to not more than five.

It would perhaps be well for us not to adopt the frame of mind of our illustrious Founder who, you will remember, made fun of those who weighed air.

It was considerations of the kind I have just outlined that led Council to put before our corporate body the desirability of increasing the number of Fellows to be elected annually. It is not the policy of the Society to allot a special number of places to any one subject or group of subjects, but it was the firm intention of this year's Council that a substantial number of the new places should be given to applied scientists on both the physical and biological sides, and that consideration should be given to electing some Fellows in some of the disciplines at present not represented or, if represented, inadequately so.

The Society by its present action is deliberately proclaiming its special interest in the marvellous developments of modern technology and in those who are responsible for them. We are confident that new technologically oriented Fellows will strengthen the Society, and we also hope that our increased interest in these matters will go some way to convince our technological colleagues that we are interested in them and all they mean to the nation.

It has been argued and indeed publicly proposed that Britain needs a new Academy, similar to the Royal Society, but devoted to the application of science, particularly in engineering. The feasibility of such a proposal clearly depends in the first instance on whether applied scientists feel the need for a body with the structure of an Academy which would look after their particular interests and which could serve the country during the coming critical years. My personal view, for what it is worth, is that the Royal Society, having made its present dispositions, should watch the position carefully in the next year or two and should not shut its mind to considering how it can best help in furthering technology if there should be a genuine and widespread demand for such action. What forms this further help might take I am not prepared to say, but as the problem of dealing with the growing importance of applied science is not confined to Britain it would be advisable to pay some attention to what is happening elsewhere.

The last thing I believe we want to see in Britain is two possibly antagonistic Academies representing what might come to be thought of as incompatible interests.

In the meantime, to emphasize that the Royal Society, while not diminishing in any way its interest in the more traditional natural sciences, is in earnest about widening its scope, there are to be four special occasions during next year at which two lectures on applied science will be given particularly for the information of Fellows, and there will be two lectures on economics and social anthropology, financed by a generous donation from the Nuffield Foundation. It is planned to arrange a similar series of lectures for 1966.

In conjunction with the Engineering Institutions Joint Council, the Society is arranging a conference for headmasters and others interested in education, with the object of letting it be known as widely as possible that the applied sciences offer just as splendid careers as the so-called 'basic sciences'.

Government and Science

The Society, ever since its foundation, has given advice to the Government when called on to do so. Indeed, we owe our rent-free accommodation to the fact that H.M. King George III was very much gratified at the assistance that the Society gave him.

In the penultimate paragraph of his last anniversary address, Sir Cyril Hinshelwood said: "There are plenty of problems ahead. For example, our long, and, though informal, immensely important relations with the Government are in process of adaptation to the vast scale and complexity of scientific activity to-day. The optimum solution of this problem is of the greatest importance both to the Society and to the country. Of equal importance is the establishment among the Fellows of the right balance between the pure and the applied sciences to enable the Royal Society to maintain its full influence in the modern world". You will have noted that we have done something about his last suggestion, and I should now like to spend a few minutes on his first.

We are at a stage in the organization of science in which the involvement of Government in the affairs with which scientists traditionally deal, and the dependence of science on the public purse, introduce important problems because the days have largely passed when scientific enquiry is conducted by individuals in isolation—indeed, in many respects the ability to conduct research at all now depends on complicated Government organization.

In the present age there has been an efflorescence of Government-sponsored councils, committees, boards and authorities, and on these many Fellows of the Society sit and thus help science and the country by their advice and activities in one way or another. But the fact must be faced that because of the establishment of these numerous bodies to which the Government turns for advice in the first instance, the direct relation of the Royal Society to Government has been diminishing during the development of the scientific activity of the twentieth century.

It thus becomes of particular interest to examine what part the Royal Society can play specifically in the contemporary scene, or at least in that part of it which I am going to mention to-day.

Scientists are perhaps becoming more self-conscious about their activities and their aspirations, and about how these can optimally be fitted into the social structure. The Society as a collection of individuals from a wide spectrum of scientific activities has the advantage of being closely in contact with those who actually make discoveries, and I hope that with our new arrangements for increased representation of applied scientists in the Society we shall be in even closer touch with technology than we are at present. It may well be that we can increase our usefulness to science if we review at this time the methods by which we can furnish information and advice to the Government on a variety of topics if it so wishes.

During the past few years the Council of the Society has made its opinions known to Government about the way in which it would like to see governmental science organized, and I am happy to say that in broad outline the proposals of the present Government have taken note of the opinions that we have expressed. The pattern is emerging that there is to be a Secretary of State for Education and Science with a Minister of State who deals with the universities and Research Councils. These Ministers are to be advised by a Council for Scientific Policy which will be concerned with the consideration in broad terms of how the nation's resources are to be deployed for civilian science. In addition to the Medical and Agricultural Research Councils there is to be a Science Research Council, which will take over some of the functions of the Department of Scientific and Industrial Research, and a Natural Environment Research Council. In addition there is a Minister of Technology who is to have an advisory body composed of scientists and others. The object of this arrangement is to see whether further impetus can be given to our use of technology, and that not necessarily of the so-called 'advanced' variety.

These bodies with their numerous sub-committees now require the time and energy of a substantial number of scientists, and this imposes a severe dilemma on many of our colleagues who are still very active in their research and do not wish to be swallowed up in an administrative machine. Some scientists have for this reason a most difficult problem to face in determining the allotment of priorities for the time and energy they have available.

I am sure that Fellows would like to see the establishment of a body or bodies which would have their confidence and on which they could rely to see that organizational matters were kept constantly under review, in order that big decisions on the deployment of national resources for scientific and technological purposes should only be taken

after the best possible advice had been given to politicians, and in order that reasons for decisions should be made clear. But the supply of suitable people for these advisory jobs is somewhat limited, and it will become still more limited if many more good scientists become vice-chancellors, for I am sure it has not escaped your attention that the last three to be appointed are distinguished Fellows of the Society.

Nevertheless, over the years it has been well established that scientists are prepared to devote some of their time to helping the organization of scientific effort at the Government level. We have probably all sat on various committees and councils and tried to do our best in the interests of science and of the country. Many of us have kept up with the products of that menace of modern civilization, the duplicator, by hastily thumbing over the papers for a meeting in a train, or, if we live in London, at the meeting itself.

We should perhaps be asking ourselves whether the complications of modern organization and the size of Government commitments to science and technology any longer permit this somewhat amateur approach. But our Fellows should be aware of what they may be attempting by becoming more involved in Government, for, as R. C. Wood has said: "Men steeped in the tradition of empirical investigation undertake to compete with men versed in the dialectic whose scholarship is heavy with syntax and intrinsically barren of the scientific perspectives of even the social sciences. Men oriented towards the concept of change face men who by tradition are history oriented". Nevertheless, I consider it the duty of the Fellows of the Society to do all they possibly can to assist Government in the present somewhat critical stage of Britain's development.

Perhaps one of the services that the Society could now render to science would be to initiate a study of just how scientific opinion is brought to bear on government, so that we can have some clearer guide than exists at present through the complexities by which opinions are formed and decisions reached on scientific matters.

The Society as such has assumed no stance in the matters that I have been discussing. I merely wish to convey to you that active thought is being given to them, for they may well be of great importance to the well-being of science in the future. One reason for the Society to take an increasing interest in these matters is that the direct link with the Treasury which has existed for more than a hundred years has been broken, for we now deal with the Department of Education and Science. I cannot let the occasion pass without recording the Society's gratitude to the many able and sympathetic men it has dealt with in the Treasury. I am happy to say that we enjoy good relations with the Government, and I am sure that, while not becoming an arm of Government, we can perform a useful national service by maintaining a close collaboration with those who control our destinies.

In spite of some new commitments the traditional activities of the Society are not diminishing, indeed it can be said that we have had more than the usual number of stimulating discussions and lectures during the past year or two. As you know, the work of the officers has been spread by the appointment of what are termed active 'vice-presidents'. Prof. W. T. J. Morgan has been one of these during the past three years, and the Society owes him a great debt for the service he has given, particularly as chairman of the Hooke Committee which helps so much with the arrangements of our meetings. Although he is no longer to be on Council he has consented to continue as chairman of the Hooke Committee. We are all indebted to him and I wish to thank him personally for the help he has given me, always in such a cheerful fashion.

The other active vice-president, Prof. H. W. Thompson, is also ceasing to be a member of Council. He has been of the greatest assistance to the Society, especially when he acted as 'A' Secretary during the absence of Sir William Hodge. In a wider sphere, as president of the International Council of Scientific Unions, he is rendering a great service to international science, and I hear his praises sung in many quarters for the vigour and the inspiration which he is putting into this task. We wish him well in the continuance of this work and thank him for what he has already done.

Although the officers may at times consider that they are working hard, I hope that we never lose sight of the fact that any increase in the Society's activities places great additional burdens on Dr. D. C. Martin and his staff who, as always, have laboured mightily to sustain the work of the Society. We can count ourselves very fortunate to have such an able and experienced executive staff. We are all profoundly grateful to them for the way in which they help us in so many ways, and I am sure you would wish to convey your thanks to them on this our Anniversary Day.

THE COUNCIL FOR NATIONAL ACADEMIC AWARDS

THE Council for National Academic Awards was established by Royal Charter in September 1964. Its president is Sir Harold Roxbee Cox, and there are 21 members. The Secretary of State for Education and Science has appointed Mr. C. R. English and Mr. J. A. R. Pimlott as assessors, and Dr. J. G. Strachan has been appointed an assessor by the Secretary of State for Scotland.

The Council has powers to award first and higher degrees to students in educational establishments other than universities. It intends to use the powers given to it, and its work will thus extend beyond that of its predecessor, the National Council for Technological Awards, whose responsibilities it will take over. The latter has, with outstanding success, developed awards in technology at honours degree level for students at educational establishments other than universities: the Robbins Committee stated that the Council has been one of the influences which have brought the work of the colleges of advanced technology to its present high standards. The new Council intends to continue the work of the National Council for Technological Awards and to extend the provision of awards at honours degree level to other fields of higher education outside the universities. At the same time the Council intends to give attention to the desirability of degrees of a different type and at a different level as mentioned in the Robbins Committee's Report.

It will thus be apparent that, from the outset, the Council will need to consider a number of matters of the highest importance relating to the development of higher education in Great Britain. Thus it would be unrealistic to expect the Council to announce in the immediate future its final policy on all the aspects of higher education with which it will have to deal. At the same time, the Council appreciates it is important that the degrees it will offer should make a significant contribution to solving the problems which will arise during what the Robbins Committee described as the "short-term emergency" when children born in 1947 and the years immediately following become of university age. Therefore, it is the Council's intention to publish statements from time to time indicating those matters on which it has reached decisions and those which are being considered, with the view of enabling colleges to submit proposed courses to the Council as soon

as possible and to plan other courses which they expect will lead to the Council's degrees.

The Council wishes colleges which will offer courses leading to its degrees, and other interested organizations, to have an opportunity of contributing to its discussions, and, as will be seen, it invites comment on a number of the matters mentioned later in this article. The Council believes that the most useful form of comment from colleges would be brief statements of the appropriate courses which they have in mind as leading to the Council's degrees: it would be convenient to the Council if such statements dealt very briefly with the aims of a proposed course, the way in which the course is intended to achieve those aims, the entry qualification to the course, and any other items which the college thinks will enable the Council to make a preliminary appreciation of the proposed course.

The Council has decided, in the first instance, to set up two Boards of Studies to be known as: (1) the Committee for Science and Technology; (2) the Committee for Arts and Social Studies. This is not a final decision for all time; the Council will create further Boards of Studies if its work makes this essential.

The Council will not expect these committees to be able to deal with other than broad questions of policy relating to the nature of courses, examination arrangements, etc.; therefore, subject Boards working to the committees will also be set up. For example, working to the Committee for Science and Technology there will be an Electrical Engineering Board, a Chemistry Board and so on. These Boards will exert a powerful influence in setting and maintaining the standards of the Council's degrees in the several fields of study.

The Council appreciates that schools, colleges and present and prospective students will be anxious to know as soon as possible what degrees the Council will make available. The Council is giving high priority to a decision about the titles of its first degrees and hopes to give more information at an early date. The Council is empowered by its Charter to grant degrees to holders of the Diploma in Technology and to students who complete successfully such diploma courses which they are now attending; the Council will exercise these powers when establishing any new scheme for degrees.

The Council will take over the Diploma in Technology scheme. Until a further announcement is made about the degrees which the Council will grant to students who successfully complete Diploma in Technology courses, recommendations by colleges for the award of Diplomas in Technology to successful students should continue to be submitted in the normal way to the secretary of the National Council for Technological Awards.

Apart from any changes in the title of the award granted, the Council will continue the Diploma in Technology scheme in its present form, leaving any possible changes to emerge as the Council gains experience of the working of the scheme.

The Council is anxious that there should be no pause in the consideration of proposed new Diploma in Technology courses and is able to announce that the Boards of Studies and Subject Panels of the National Council for Technological Awards have agreed to consider proposed new courses until the Council's Committee for Science and Technology and subject Boards have been established. The Council hopes that this arrangement may need to continue for only a short period.

What is stated here about the Council's degrees applies to Scotland as well as England and Wales. Up to the present certain Scottish colleges have offered full-time courses in technology leading to their own associateships and not to the Diploma in Technology. The Council's Charter gives it power to grant degrees to students who have successfully completed or who are at present attending those courses at Scottish Central Institutions which lead to an award comparable, in the opinion of the Council, to the Diploma in Technology. The Council is considering this matter and a further announcement will be made as soon as possible.

The Council will make degrees available for students completing courses at honours level in science and technology whether organized on a full-time or a sandwich basis. The Council hopes that colleges will continue to develop the sandwich courses so successfully established under the auspices of the National Council for Technological Awards and that they will not be prevented from doing so by a shortage of places for industrial training. Colleges are invited to submit proposed courses for the Council's consideration; principals wishing to do so should consult the Council's registrar and secretary about the mechanism for the submission of the courses; but, in general, submissions should, in the first instance, be on the lines used for the Diploma in Technology courses.

As soon as a Business Studies Board has been established the Council will consider proposed honours courses in business studies planned in accordance with the report of the National Advisory Council on Education for Industry and Commerce entitled *A Higher Award in Business Studies* (the Crick Report). Colleges are therefore invited to submit proposed courses for the Council's consideration. Principals wishing to submit proposed courses should consult the Council's registrar and secretary about the mechanism for the submission of courses; but, in general, submissions should, in the first instance, be on the lines used for Diploma in Technology courses.

While the Council will not preclude full-time courses in Business Studies from leading to its degrees, it will, as a first priority, consider sandwich courses of the type recommended in the Crick Report.

If a large volume of courses in business studies is submitted for consideration the Council envisages that it may have to give priority to the consideration of courses submitted by those colleges which have already had some experience of conducting advanced courses in business studies.

The Council believes that colleges will be looking to it to provide degrees in a variety of arts subjects and the social sciences, and hopes that its Committee for Arts and Social Studies will be able in the near future to advise it on the types of courses in those fields of study for which it should grant degrees. The Council is sure that any comments which colleges, teachers' organizations, professional bodies and other interested organizations may care to submit would be of great value to the Committee in its deliberations.

Experience seems to indicate that colleges may wish to offer courses which extend over more than one field of study, for example, courses embracing studies in technology and social sciences. The Council would like to give thought to such courses and would be interested to hear the comments of colleges and other interested organizations who may wish to submit observations.

The Council proposes to examine the case for the development of courses in science and technology at ordinary degree level and would be interested to see outline proposals from colleges which have in mind to offer courses at this level.

Undoubtedly the Council will for some time be preoccupied with the consideration of the honours degree courses recommended in the Crick Report, and there may be a delay before the Council can examine the case for ordinary degree courses in business studies. However, if a college submitting a proposed honours course on the lines of the Crick Report intends to offer in the future also a complementary course at ordinary level, the Council would be interested to see outline proposals of the latter at the same time as it examines the honours course.

The Council believes that part-time students should have the opportunity of gaining its degrees. Further consideration will be given to the nature and length of the part-time study which will be required.

In addition to granting degrees the Council is empowered by its Charter to grant diplomas and certificates comparable with those awarded by universities. The Council will consider the ways in which this power shall be exercised.

The Council believes that it will need to offer higher degrees both at master and doctor level. However, some time may elapse before the Council can make a firm statement on this point, since it must obviously give first priority to the establishment of its first degrees.

The Council will ensure continuity of the award of membership of the College of Technologists by taking over this work from the National Council for Technological Awards as soon as this can be arranged, and details will be announced in the very near future. As part of the long-term consideration of the higher degrees it will offer, the Council will consider whether in due course one of its own higher degrees shall be granted for programmes of work of the type which now lead to the award of membership of the College of Technologists. If any changes are made these will apply also to the holders of the award and to students working for it.

Further information, including fees, etc., can be obtained from the registrar and secretary, Mr. F. R. Hornby, Council for National Academic Awards, 24 Park Crescent, London, W.1.

THE *SPARTINA* STORY

TO-DAY, even the layman is often aware that a vigorous new maritime grass has become increasingly widespread around the coasts of Britain, and now forms conspicuous swards on many tidal flats. It is less commonly realized, however, that this large and aggressive newcomer, of the genus *Spartina*, was completely unknown a century ago. Under the title of "The *Spartina* Story", current work concerning its origin, present ecological status and economic value was brought together at a meeting of Section K (Botany) of the British Association for the Advancement of Science on August 26 at Southampton; since the grass originated on the shores of Southampton Water, the location of the symposium was particularly apt.

The symposium was introduced and chaired by Dr. C. E. Hubbard (deputy director of the Royal Botanic Gardens and keeper of the Herbarium at the Royal Botanical Gardens, Kew), who discussed the general taxonomy and distribution of the grass; Dr. C. J. Marchant (also of Kew and formerly of the University of Southampton) considered its origin in the light of recent cytological investigations; Dr. J. M. Lambert and Prof. W. T. Williams (both of the University of Southampton) dealt respectively with ecological work on the grass and with possible physiological causes of the incidence of 'die-back' in some swards; and Dr. D. S. Ranwell (Nature Conservancy) summarized the broader aspects of the establishment of *Spartina*, with particular reference to its use for economic purposes and its general significance to man.

The story formally begins with the recognition and description of the grass as a new species, under the name of *Spartina townsendi* (later *townsendii*), by the brothers H. and J. Groves, from material collected near Hythe in 1878. Investigations have since revealed that previous collections were made in 1870 and possibly even before, and that the early material (including the type specimen) consisted of sterile plants. Later collections, however, were principally of a more robust, fertile grass, and—pending taxonomic revision—the name *Spartina townsendii* is commonly still used indiscriminately to cover both sterile and fertile material.

From the time of its first discovery as a hitherto unknown British plant, there has been much speculation concerning the origin of the grass. Suggestions included accidental introduction from the United States, mutation of an existing species, and hybridization. The last possibility was made particularly plausible by the fact that the new *Spartina* was morphologically intermediate between two other species which existed together in the locality at the time, namely *S. maritima*, native to Britain, and *S. alterniflora*, a North American species believed to have been introduced accidentally by shipping into the Southampton area in the early nineteenth century.

In 1931, C. L. Huskins published an investigation of hereditary relationships in 'British' representatives of *Spartina* from cytological findings. Unaware of the existence of the sterile plant, he gave the chromosome complement of fertile *S. townsendii* as $2n = 126$, and derived it by chromosome doubling from a hypothetical 63-chromosome hybrid between *S. maritima* ($2n = 56$) and *S. alterniflora* ($2n = 70$). Unfortunately, Huskins's results were thrown open to doubt by the fact that, believing *S. alterniflora* to have become extinct in its former British locality, he made his counts for this polymorphic species on American material; moreover, the cytological techniques available at that time were inadequate for examining the small chromosomes of *Spartina* with any degree of precision.

In his recent re-investigation of the situation, C. J. Marchant was not only able to use modern techniques, but also to find and examine British material of *S. alterniflora* still surviving in the Southampton Water area. Both sterile and fertile plants of *S. townsendii* were included in his investigations, and chromosome counts from a wide range of material gave the following numbers: *S. maritima* 60 (never 56); *S. alterniflora* 62 (never 70); sterile *S. townsendii* 62; fertile *S. townsendii* variable with 120, 122 (commonest) and 124. Although the new counts provided a numerically less-exact scheme of relationships than that suggested by Huskins, the postulated origin of fertile *S. townsendii* by hybridization and subsequent chromosome doubling was nevertheless supported. The hybrid nature of the sterile plant was attested by irregularities in chromosome pairing at meiosis, while careful comparison of chromosome morphology confirmed its derivation from *S. maritima* and *S. alterniflora*; in contrast, the 120- to 124-chromosome form of *S. townsendii* showed almost regular pairing, while the discovery of other *Spartina* plants, intermediate in external form and chromosome number (90 and 76), suggested back-cross links between *S. townsendii* and *S. alterniflora*.

Because of the interest aroused by the first appearance of *S. townsendii*, the subsequent spread of the grass has been recorded by botanists in detail. Much of its early spread from its original station near Hythe was by natural means, and by 1915 it was established in every south-coast estuary from Chichester to Poole. From the early 1920's onwards its range was greatly extended by artificial plantings, and it now covers at least 30,000 acres of tidal flats around the British Isles alone.

The story of *Spartina* in Britain, however, is not solely one of uninterrupted success in the occupation of new habitats. Within the past 40 years there have been a number of reports of patchy degeneration—'die-back'—of previously healthy *Spartina* swards. This problem was recently investigated by P. J. Goodman and Mrs. E. M. Braybrooks at the University of Southampton. Their detailed surveys showed that the pattern of die-back seemed remarkably constant in affected areas, with 'channel die-back' along the edges of the major creeks, 'pan die-back' in low-lying areas in the middle of marsh segments, and healthy *Spartina* on slightly raised banks

or *levées* nearer the creeks. There was no evidence to associate the incidence of die-back with pollution or pathogen attack; indeed, both field observations and transplant experiments suggested strongly that die-back resulted from the establishment of locally unfavourable habitat conditions.

The reason for die-back pan formation in previously healthy swards was elucidated by means of soil borings. In a number of different sites, levelled lines of bores showed that a decrease had occurred in the general slope of the marsh from back to front following colonization by *Spartina*; the grass had caused greater mud accretion at the front, and drainage of the marsh surface had been progressively impaired. Similarly, bores across marsh segments lying between adjacent creeks gave evidence of a change from a convex to a concave profile for the intervening marsh, resulting in more or less permanently waterlogged conditions in the centres of the segments. The appearance of die-back pans thus resulted from the normal physiographical development of the sward: *levées* had been produced by mud filtered from the tidal water by the *Spartina* plants themselves, and surface run-off from the marsh had thereby been locally impeded. The cause of channel die-back was less certain; but it may have been due to the slipping of soft mud back into the channels, bringing the neighbouring marsh surface down to a level too constantly flooded for healthy *Spartina* growth.

Although the field evidence strongly suggested an ecological connexion between *Spartina* die-back and excessive wetness of the soil, the physiological explanation of such die-back was by no means clear. Symptoms of die-back included death of underground buds and soft-rotting of the rhizome apices, but such symptoms could be due to a number of causes. The deleterious effect of water-logging on plants is commonly attributed to lack of oxygen in the soil; but this again could operate in several different ways—by causing toxic substances like alcohol or acetaldehyde to accumulate in the tissues as a result of anaerobic respiration, by interfering with some important vital process, by producing poisonous substances like ferrous salts, sulphides or nitrites in the soil, or by predisposing the plant to bacterial or fungal attack by any of these mechanisms.

Laboratory experiments, carried out at Southampton by P. J. Goodman, Miss S. Barker and A. Ivemy, and discussed by Prof. Williams, have now reduced these possibilities to that of interference with some vital but unidentified function in the plant. Alcohol- and acetaldehyde-levels in die-back plants were too low to be critical for growth; the presence of bacteria in *Spartina* rhizomes was not consistently associated with die-back; and, although high concentrations of sulphide were present in die-back soils, no quantitative relationship could be established with rhizome apices cultures at different sulphide-levels, while, on the other hand, die-back symptoms could be produced in the absence of sulphide when oxygen was excluded from the cultures. It is certainly possible that soil sulphides are indirectly responsible for die-back by forming an oxygen sink, but the basic physiological effect of lack of oxygen still remains essentially unresolved.

Whatever may be the ultimate cause of die-back in *Spartina*, once it is initiated in a sward the weakened areas may be enlarged by tidal scour so that the sward becomes progressively disintegrated. At present, the phenomenon of die-back is very restricted in extent, and limited to marshes on fine-textured soils with exceptionally poor subsoil drainage. In other *Spartina* areas with coarser soils it is probable that more stable conditions will result; most swards are still too young for their ultimate fate to be predicted with any certainty.

Although *Spartina* seems susceptible to continuous water-logging, it nevertheless appears more tolerant of wet conditions than many other salt-marsh plants. It thus tended in the first place to colonize bare mud flats in front of existing salt-marshes, and this type of situation is sometimes regarded as its exclusive habitat. However, there is increasing evidence that it is now also migrating backwards into older saltings and ousting the original salt-marsh vegetation.

One such investigation of the successful invasion of pre-existing saltings was carried out by Miss Barker at Southampton, with particular reference to the mechanism by which *Spartina* replaces *Juncus maritimus*, a tall-growing species which normally occupies the higher and drier salt-marsh zones. A number of soil borings made in critical sites established that the entry of *Spartina* had greatly accelerated the rate of mud deposition where it had invaded, so that, whereas the high-lying *Juncus* zone had previously been freely drained, it was now thickly flanked by recently accumulated mud. Morphological and anatomical investigations of plants from the disappearing *Juncus* zone suggested that *Juncus* was showing the same die-back symptoms as were exhibited by *Spartina* under more extreme conditions; its replacement by *Spartina*, therefore, appeared to hinge on its greater susceptibility to impeded drainage rather than on a more direct competitive effect.

The power of rapid mud accretion by *Spartina* has long been recognized as one of its outstanding characteristics as a salt-marsh plant. In fact, its potential value for stabilizing and reclaiming inter-tidal flats was realized as early as the beginning of this century, and many thousands of cuttings and seeds have since been distributed to various parts of Britain and to more than 40 countries in different parts of the world. Dr. D. S. Ranwell and his colleagues in the Nature Conservancy have recently collected much information on the distribution and use of *Spartina* for economic purposes, and their survey indicates that *S. townsendii* now covers a world total of some 70 square miles or more.

Outside the British Isles, the establishment of *S. townsendii* has been most successful in the Netherlands, France and Germany. Its present known geographical limits are between 48° and 58° N. on European coasts. It has also been introduced successfully at 48° N. on the western seaboard of the United States, but plantings have failed at 45° N. on the colder eastern side. In Australia and New Zealand it survives between 35° and 46° S. Where otherwise suitable habitats exist, it seems to be restricted by frost damage on the polar sides of these limits. On the equatorial side, it apparently succeeded for a few years on the coast of British Guiana only 7° N. of the equator, but was finally smothered in competition with the native species *S. brasiliensis*; so far as is known, it has not survived in any other tropical sites.

In Britain itself, the primary use of *Spartina* has been for coast protection. A very successful example of this is seen at Bridgwater Bay on the Somerset coast, where a 2·5-mile length of the coastline has been effectively protected and the foreshore-level raised by 5 ft. since *Spartina* was planted in 1929. A similar use has been made of the grass in the Mitchell estuary and around the Gippsland lakes in Australia, and in the South Island of New Zealand.

In the Netherlands, Denmark and Germany, and also on a smaller scale in Britain round the Wash, *Spartina* has been used mainly for reclamation purposes. Perhaps the biggest and most successful reclamation experiment was that carried out in the Sloe Dam area in Holland, where large-scale planting started in 1925; by 1949 the first *Spartina* polder was ripe for reclamation, and the whole area is now a settled agricultural district. In northern Holland, planting of *Spartina* was at first less successful, and all but about 1 per cent of the initial transplants from south Holland were killed by winter frosts; with later selection and propagation of winter-hardy forms, however, there are now extensive *Spartina* meadows along the Groningen coast.

It was Prof. F. W. Oliver, one of the pioneer investigators of *Spartina* in Britain, who realized that the new

British grass had potentialities not only for reclamation but also as a crop. Its food value to stock is roughly equivalent to that of medium-quality hay, and it seems to be relished by a wide variety of herbivores. Although it has proved too coarse for the highly bred livestock of countries like Holland and Denmark, the older breeds of domestic animals graze freely on *Spartina* when it is available. Because of the difficult terrain on which it grows, there have been few attempts actually to harvest the grass. However, an experiment at Bridgwater Bay has shown that in suitable areas it is possible to cut and transport *Spartina* using light machinery, and the cut material is being tested for possible use as silage.

In spite of its economic value, the advent of *Spartina* is not an unmixed blessing. The very rapidity with which it can spread and transform a habitat can itself be a cause of trouble in certain circumstances. Fears that it would block major navigation channels in harbours have proved unfounded; but in estuarine marshes it sometimes chokes minor channels used by yachtsmen. Again, where it invades mud-flats near holiday beaches, the amenities of the area may be spoiled, and the beaches themselves eventually obliterated. Further, from a conservation angle, there is a very real danger that certain forms of wild-life may be lost in coastal areas overrun by the grass; other salt-marsh plants may be eliminated, the feeding grounds for wintering wild-fowl covered, and variety in the marshes reduced at the expense of the spread of a single species. Control measures for *Spartina* are under investigation, however, and some success has been achieved with carefully timed applications of some of the more innocuous herbicides.

In all, the *Spartina townsendii* story is clearly one of importance from both an academic and a practical point of view. Its main scientific interest lies in its exemplification of the evolution of a new species under natural conditions by hybridization between two geographically isolated species brought together by chance, restoration of fertility by chromosome doubling, and successful establishment in a vacant ecological niche. Man has not been slow to take advantage of the particular ecological and physiological properties of the new species which have contributed to its success; and it is perhaps ironic to note that it is just these marsh-building properties which may have hastened reclamation and industrial development along the Southampton Water shores, so that the classic birthplace of *Spartina townsendii* is now threatened with extinction.

J. M. Lambert

NEWS and VIEWS

Genetics in the University of Birmingham: Prof. J. L. Jinks

Dr. J. L. Jinks, at present honorary reader in genetics in the University of Birmingham, has been appointed to the chair of genetics in succession to Prof. K. Mather, who has been appointed Vice-Chancellor of the University of Southampton (*Nature*, 203, 24; 1964). Dr. Jinks gained both his B.Sc. and his Ph.D. at the University of Birmingham. He graduated in botany in 1950 and was awarded a research studentship in genetics by the Agricultural Research Council, which he held in the Department of Genetics in the University, obtaining his Ph.D. in 1952. Following his research studentship, he was appointed to the staff of the Agricultural Research Council's Unit of Biometrical Genetics, attached to the Department of Genetics, and has continued in this appointment up to the present time. He spent a year as a Harkness Fellow at the California Institute of Technology, and has worked for shorter periods in Copenhagen and Milan. Dr. Jinks's research has been mainly concerned with inheritance in moulds, bacteria and viruses, how they adjust themselves to their environments and how those which cause diseases of domestic plants adapt themselves to attack their hosts. He has also investigated the inheritance of characters which, like yield in domestic plants and animals, vary by imperceptible gradations over a wide range of phenotypic expressions. The methods of analysis that he has devised for such characters are now in wide use by plant breeders and have also led to important advances in the understanding of the hereditary determination of behaviour in animals. Dr. Jinks's appointment will take effect from October 1, 1965.

Agricultural Chemistry in the University of Leeds: Prof. J. A. F. Rook

Dr. J. A. F. Rook, principal scientific officer in the Chemistry Department of the National Institute for Research in Dairying, Shinfield, has been appointed to the chair of agricultural chemistry in the University of Leeds. Dr. Rook was educated at Scarborough High School for Boys and the University College of Wales, where he graduated with first-class honours in chemistry with agricultural chemistry in 1947. He held an Agricultural Research Council research training grant from 1947 until 1950 and spent two years in the Chemistry and Physics Department of the National Institute for Research in Dairying, followed by one year in the Department of Animal Physiology and Biochemistry of the Danish State Agricultural Research Laboratories, Copenhagen. He gained a Ph.D. degree at the University of Glasgow in 1957 for a thesis on "Some Studies on Energy Metabolism". In 1950 he was appointed scientific officer at the Hannah Dairy Research Institute, Ayr, and three years later was promoted to senior scientific officer. He returned to the National Institute for Research in Dairying in 1954, as senior scientific officer, and has held his present appointment as principal scientific officer in the Chemistry Department of that establishment since 1961. Dr. Rook's research interests include magnesium metabolism in calves and dairy cows, milk composition and metabolism and milk secretion.

Applied Mathematics in the University of Liverpool: Prof. J. G. Oldroyd

Prof. J. G. Oldroyd, professor of applied mathematics in the University College of Swansea, has been appointed to the newly established second chair of applied mathematics in the University of Liverpool. Prof. Oldroyd is forty-three years of age and was educated at Bradford Grammar School and Trinity College, Cambridge, where he won the Rouse Ball Mathematical Prize in 1941, the Mathison Prize in 1942, and successfully completed the Cambridge Mathematical Tripos Part III with distinction in 1942; he was awarded a B.A. degree in 1942, M.A. in 1946, Ph.D. in 1949 and Sc.D. in 1958. From 1942 until 1945 he served as an experimental officer with the Ministry of Supply, undertaking theoretical research mainly on the internal ballistics of rockets. From 1945 until 1953 he held the post of mathematical physicist at Courtaulds' Fundamental Research Laboratory at Maidenhead. He was a Fellow of Trinity College, Cambridge, from 1947 until 1951. In 1953 he was appointed professor of applied mathematics at University College of Swansea and became head of the Department of Applied Mathematics when it was created in 1957. Prof. Oldroyd has served as Dean of the Faculty of Science at Swansea, as a member of the College Council, a member of the Academic Board of the University of Wales and a member of the University of Wales Commission. From 1955 until 1957 he was president of the British Society of Rheology. Prof. Oldroyd will take up his new appointment on January 1.

Physiology in the University College of Rhodesia and Nyasaland : Dr. J. D. Nelms

Dr. J. D. Nelms, at present research medical officer in the Climatic Research Laboratory of the Institute of Aviation Medicine attached to the University of Birmingham, has been appointed head of the Department of Physiology in the University College of Rhodesia and Nyasaland from a date to be arranged. Dr. Nelms gained an honours B.Sc. degree in physiology at University College, London, in 1953, and qualified with the degrees of M.B., B.S., in 1955. He joined the Royal Air Force in 1957 and has since that time worked in the Institute of Aviation Medicine, during the past four years as a research medical officer. His research work has been mainly concerned with the effects of climatic environment on man. He was largely responsible for the development of new and modern methods of heating the body by electrically warmed underclothing. He has collaborated in two international expeditions to investigate the physiological basis of acclimatization to cold—one among Arctic Indians in the Yukon Territory.

Pharmacy in the Hebrew University, Jerusalem: Prof. M. Donbrow

Dr. Max Donbrow, principal lecturer in the School of Pharmacy of Chelsea College of Science and Technology, has been appointed professor, and head of the Department of Pharmacy in the Hebrew University of Jerusalem as from January 1965. His published research is concerned with the application of physical methods to the analysis of drugs, the properties of surface-active agents and the uptake of drugs by non-ionic surfactants. He is at present working on complex-formation between drugs. Dr. Donbrow spent several months in Israel in 1963 advising on the development of the Pharmacy School in the Hebrew University, and modifying the curriculum. The foundation stone for the new Pharmacy School was laid in August this year at the Medical Centre in Ein Kerem, and the existing Pharmacy School is expanding at once into premises vacated by the Medical School in the Russian Compound in Jerusalem.

Nuclear Physics in the Weizmann Institute of Science: Dr. Peter Hillman

Dr. Peter Hillman has been appointed head of the Department of Nuclear Physics at the Weizmann Institute of Science at Rehovoth, in succession to Prof. Amos de-Shalit, who has held the post since 1954. Prof. de-Shalit remains in the service of the Institute but has assumed a wider range of duties. Dr. Hillman has been on the staff of the Institute since 1960 and has acted as head of the Department on several occasions. Born in Durban, he was educated in South Africa and at Harvard University, where he received the M.A. and Ph.D. degrees. He later worked in Britain and in Sweden, and was for a time lecturer in the University of Witwatersrand.

Marsa el Brega : an International Oil Port

Some remarkable records of discovery, development, exploitation and marketing of crude petroleum from a new oilfield are disclosed in an article in the summer issue of *Esso Magazine* (13, No. 3, 1964; Esso Petroleum Co., Ltd., London), judged even by modern oil-company standards. It was in 1954 that geological search for oil in the then wilderness of northern Libya started in earnest, resulting in the discovery in 1959 of what is now known as the Zelten field, some 100 miles or so inland from the Mediterranean coastline. The problem of getting the oil away to the tankers came next. The intervening territory was barren and desolate, save for some half a million land mines strewn around, left over from World War II. Aerial surveys of the Gulf of Sirte coastline pointed to a place called Marsa el Brega, some 114 miles S.W. of Benghazi, as a potential harbour, with reasonable shelter and off-shore depth of water to accommodate the largest tankers afloat. In 1960, 110 miles of road between Marsa el Brega and Zelten were completed and soon afterwards some 115 miles of 30-in. pipeline were emplaced alongside the road. In September 1961, the first shipment of oil left the port of Marsa el Brega for the Esso refinery at Fawley. In the meantime, another commercial-size oilfield was discovered at Raguba, 45 miles N.W. of Zelten, and a spur pipeline from this area was completed early in 1963. "As a measure of what had been achieved in a very short span of time, over 6 million tons of oil were exported from Marsa el Brega in 1962, the first full year of operation. . . . As a result of . . . continued activity, over 14 million tons of oil were exported during the 12 months of 1963." Marsa el Brega, which so short a time ago was nothing more than rock, sand and water, is to-day an international oil port in every sense of the word; it is used by tankers of many different countries, including Britain, West Germany, Italy, France, Holland, Belgium, Spain and Egypt; it has helped to establish Libya as a major oil-producing country, a timely addition to the diverse and ever-growing oil resources available to the world.

The Museums Journal

The September issue of *The Museums Journal* (64, No. 2; September 1964) includes an article on the extensive modernization which has been carried out at the Whitworth Gallery, Manchester. The collections include early and contemporary water-colours and textiles with some sculpture and oil paintings. The main objects of the work were to raise existing facilities in the Gallery to advanced modern standards in respect of conservation, display, circulation and supervising, and storage facilities. Dr. M. Eager describes an excellent and modern display concerning the Moon which has been set up in the University Museum at Manchester, and Mr. W. A. Seaby details the proposed extensions to the Ulster Museum in Belfast. A report of the annual conference in Nottingham in July completes the issue.

Caspian Sea and Siberian Rivers

Until 1929 the level of the Caspian Sea was more or less constant, but since then its level has fallen by 2·5 m, corresponding to a loss of 960 cubic kilometres of water—four times the volume of the Volga's annual discharge. According to B. A. Apollov and S. N. Bobrov (*Priroda*, 2, 68; 1963) such an enormous fall in level is seriously threatening navigation, fisheries and other industries. Several projects aimed at raising the level of the Sea have been proposed. One of them was to dam the Rivers Yenisey and Ob and discharge them into the Aral Sea and then let the waters flow into the Caspian along the old drainage channel of Uzboy. Another project was to increase the Volga's volume of water by diverting into it the Rivers Pechora and Vychegda. Apollov and Bobrov are of the opinion that both these projects are impracticable, and instead suggest the construction of an earth dam across the northern part of the Caspian Sea so as to form a separate North Caspian reservoir. Another project is that of I. I. Stas' (*Priroda*, 2, 75; 1963), who proposed to link up by canals the Azov, Caspian and Black Seas. Projects of damming the Siberian Rivers Ob, Yenisey and Lena are discussed by V. S. Antonov (*Priroda*, 6, 25; 1963), Yu. I. Gordeev (*Priroda*, 6, 51; 1963), M. A. Shargaev (*Priroda*, 6, 54; 1963) and V. I. Orlov (*Priroda*, 6, 59; 1963).

Glued Formwork for Concrete

In a recent note on modern gluing techniques as applied to laminated wood in timber structures for buildings (*Nature*, 204, 129; 1964), attention was directed to the versatility of this form of construction under certain conditions where its entry had proved architecturally admissible. It was but a step to adapt the principle

involved to another constructional problem, this time a vital question of formwork for concrete as used in the 540-MW hydro-electric scheme in New Zealand; this is what is known as the Benmore project on the Waitak River, South Island, designed to ". . . contain six 90,000-kilowatt generators producing 540 MW of electricity" and ". . . will feed into the national grid, which, by means of a cable under Cook Strait, will supply the North Island as well . . .". According to an article entitled "Aerolite-glued Formwork for Concrete", some 450,000 cubic yards of concrete are involved in this project, most of which was cast using timber formwork (Ciba (A.R.L.), Ltd. *Technical Notes*, No. 259, July 1964. Pp. 8. Duxford: Ciba (A.R.L.), Ltd., 1964). In concrete construction, especially for river dams such as this, there is a recent tendency towards larger and higher pours; formwork therefore has to withstand greater pressures than before. When the motive is also economy, there is a rational trend towards the use of units which can be used repeatedly; essential criteria are extra strength, quick release and easy handling. "It was found that all these characteristics could be facilitated by the use of glue laminated timber structures incorporating Aerolite adhesive." In a report by D. R. Douglas, structural design draughtsman on this project, quoted in the article, he remarks on the big advantages obtained by the use of glue laminated work. "The choice of laminating or of using solid timber for forms was determined mainly by the importance of the component in relation to the whole form or by the need for stability or alignment. With a rainfall averaging 15 in. or less per year, and with the very low humidity of the district, all timbers dried out and tended to distort more than they would have in many other places. For this reason alone, the lamination of critical members was preferred." The several excellent illustrations accompanying this article clearly show the manner in which this glued formwork is prepared, assembled and used; it is a technique which will become increasingly popular in similar circumstances elsewhere.

Palæontology in the U.S.S.R.

The recent volumes of the *Transactions of the Palæontological Institute (Moscow)* (*Nature*, 197, 854; 1963; 199, 1139; 1963) are: (98) Bryozoa of the Borshchovsky and Chortkovsky horizons of Podolia, by G. G. Astrova (1964). These two horizons were originally placed in the Upper Silurian, but the present author proves them to be of Lower Devonian age; 150 specimens belonging to 24 species are described. (99) Biometric study of Pliocene vivipari of the southern part of the U.S.S.R. by V. Ya. Taboyarkova (1964). (100) The historical development of Diptera, by B. B. Rodendorf (1964). (101) Tabulates of the Lower and Middle Devonian age in the Kuznetsk Basin, by I. I. Chudinova (1964). (102) Conditions of life of the Silurian and Devonian marine fauna in the Kuznetsk, Minusinsk and Tuva Basins, by E. A. Ivanova, T. N. Bel'skaya and I. I. Chudinova (1964).

Bleeding in the Surgical Patient

Surgeons throughout the world can scarcely fail to be interested in the recent issue of the *Annals of the New York Academy of Sciences* entitled *Bleeding in the Surgical Patient*, in which 68 experts, who met at a conference held by the Academy in May 1963, discuss various aspects of the general problem of bleeding during, or after, surgical operations (115, Article 1. By Seymour Gollub, Alex W. Ulin and 77 other authors. Pp. 1–542. New York: New York Academy of Sciences, 1964. 7 dollars). This has been and, as the first paper in this series explains, still is, a fundamental problem for the surgeon. Great advances in the control of hæmorrhage have, of course, been made since Lister showed that blood vessels could be ligatured. Nowadays the detailed biochemical investigation of the various factors concerned in blood coagulation would seem to be in the foreground, but hypothermia, blood transfusion, advances in anæsthetics and a number of other factors discussed here have also played important parts in the reduction of the consequences of operations and the mortality formerly due to them.

Congenital Absence of Pain

Dr. H. J. Kingsley and Dr. J. E. A. David of Bulawayo have described (*Central African Journal of Medicine*, 10 (8), 1964) the case of a girl aged 22 months. She was subject to temper tantrums, and during these tantrums would bang herself on the head or bite herself. She appeared to be completely insensitive to pain. She is a well-built, sturdy little girl and, apart from the bandiness of her legs and a photosensitive skin rash, no physical abnormalities were found. Mentally, it was thought she might be a little backward. She was admitted to hospital for investigation and was noticed to have periods of blankness which were thought to be some type of petit mal. Many investigations were made and all results were normal. While she was in hospital her sensitivity to pain was tested and it was found that the child was insensitive to pain almost all over the trunk, limbs and face, and a sterile hypodermic needle could be stuck through the skin to the subcutaneous tissues without any flinching. She was apparently insensitive to heat and cold and to light touch, but these were difficult to evaluate. Winkelmann and his colleagues have previously reported a case of congenital universal indifference to pain in a 9-year-old white boy, with detailed anatomical, clinical and physiological studies. Confusion exists in the literature about congenital absence of pain, and a complete neurological examination should be carried out in these cases; specific attention should be directed towards the discovery of isolated islands of normal sensation, particularly round the trunk, genitals and face. This type of insensitivity is usually congenital and the patient is usually of normal intelligence, development and psychic adjustment. In a case described by Winkelmann, Lamber and Hayles no nerve end organs (Meissner or Vater-Pacini corpuscles) were found in any of the skin specimens studied. Dr. Walter B. Shelley of Philadelphia thinks that these cases are not as rare as is supposed and that there are people who experience coronary thrombosis or a perforating appendicitis, or have babies, without pain. Apparently, where pain is absent, itching is also absent.

University News: Bradford

The Governing Body and the Academic Advisory Committee of the Bradford Institute of Technology have announced the establishment of 30 professorships. The following heads of department become the first 12 professors in the fields concerned: Dr. E. Lees (biological sciences); Dr. R. L. Elliott (chemical technology); C. W. Page (chemical engineering); Dr. C. B. Wilby (civil engineering); Dr. G. N. Patchett (electrical engineering); J. G. Jagger (mechanical engineering); T. Kempner (management); Dr. J. G. Freeman (mathematics); Dr. J. M. Rowson (pharmacy); Dr. D. L. Smare (physics); P. H. Coles (social sciences); Dr. F. Happey (textiles).

London

Dr. J. W. Boag, physicist in the Research Unit in Radiobiology at Mount Vernon Hospital, has been appointed to the chair of physics as applied to medicine tenable at the Institute of Cancer Research, Royal Cancer Hospital. Dr. E. W. Emery, senior lecturer in medical physics in the University of Manchester, has been appointed to the readership in medical physics tenable at the Postgraduate Medical School of London from April 1. The following titles have been conferred: *Professor*, on Dr. D. R. Laurence (pharmacology and therapeutics), in respect of his post at University College and University College Hospital Medical School. *Reader*, on Dr. P. N. Campbell (biochemistry), in respect of his post at Middlesex Hospital Medical School; on Miss N. F. T. Crowley (bacteriology), in respect of her post at the Royal Free

Hospital School of Medicine; on Dr. H. Urich (neuropathology), in respect of his post at the London Hospital Medical College; on Dr. P. L. Williams (experimental neuroanatomy), in respect of his post at Guy's Hospital Medical School.

Oxford

In an oration published in the annual report as a supplement to the *Oxford University Gazette* of October 2, 1964, the Vice-Chancellor announced that it had been possible, thanks to the initiative of Merton, All Souls, Christchurch and St. John's Colleges, to make a start with the creation of two new graduate societies for non-Fellows (Supplement No. 3209. Pp. 51–77. Oxford: The University, 1964. 2*s*.). A capital grant of £29,000 had been promised to the University with recurrent grants for ten years to ensure an annual income of £18,000. The Vice-Chancellor expressed the view that doors should be left open, as in the past, for those who contribute to the life of the University in other ways than as tutors or research workers. The annual report records an increase of 174 in the number of matriculated students in residence compared with 1962–63; of the 8,963 students in 1963–64, 7,558 were men. Of the total, 412 men and 60 women came from Commonwealth countries and 550 men and 80 women from other countries. Besides the establishment of two posts of University lecturer status in each of the Faculties of Physical and Biological Sciences, a new professorship was established in the Department of Engineering Science through funds made available by Messrs. Stewart and Lloyds, to cover a period of seven years in the first instance, and this professorship of structural engineering will be known as the Stewart and Lloyds professorship.

Canadian Awards in Chemical Engineering

G. C. M. MacKay and S. G. Mason (McGill University and the Pulp and Paper Institute, Montreal) have received the award of the Chemical Engineering Division of the Chemical Institute of Canada for the best paper published in *The Canadian Journal of Chemical Engineering* during the year, in respect of their paper entitled "The Gravity Approach and Coalescence of Fluid Droplets at Liquid Interfaces". In the Division's 1964 Student Paper Competition, J. Morgan (University of British Columbia) was awarded first place and I. Patterson (McGill University), second.

IBM Scholarships

Five new scholarships, together amounting to about £10,000, are to be awarded each year by IBM United Kingdom, Ltd. The scholarships will provide grants for students wishing to attend any British university. The grants will be worth about £600 per annum each, and will be available for covering a maintenance allowance and certain university fees and expenses. Such grants will be given to candidates who have obtained places at residential universities; reduced grants will be available for successful applicants who will live at home during the term. Although there will be no obligation on either side, IBM scholars will be given preferential consideration if they wish to join the Company after graduation. Initial interviews will be held in February and March, and final interviews will be held during the Easter vacation. Application forms, which should be submitted through headmasters and headmistresses, and further details are available from the Director of Personnel, IBM United Kingdom, Ltd., 101 Wigmore Street, London, W.1.

Smithsonian Observatory Post-doctoral Research Programme

A post-doctoral fellowship programme for research associates has been established at the Smithsonian Astrophysical Observatory, Cambridge, Massachusetts. Two appointments for visiting scientists from U.S. or overseas institutions will be available in January 1965 with two additional appointments available in July. The Astrophysical Observatory is one of several Smithsonian Institution bureaux which will offer such a programme in co-operation with the U.S. National Academy of Sciences–National Research Council. Research associateships will be offered to scientists pursuing post-doctoral investigations in the general fields of applied and theoretical space sciences, astronomy, astrophysics, and celestial mechanics. Two types of appointment will be available: regular associateships for scientists at the immediate post-doctoral level, and senior associateships for scientists who are five years past their doctorates and who are already engaged in research activities resulting in publication or recognition in their fields. Associateships are available to scientists from the United States and overseas. The stipend for the regular post-doctoral research associateships is 10,000 dollars per annum. Appointments will normally be for one year. The U.S. National Academy of Sciences–National Research Council will administer the programme. Further information and application forms can be obtained from the U.S. National Academy of Sciences–National Research Council, 2101 Constitution Avenue N.W., Washington, D.C. 20560.

Announcements

A symposium on "Human Palaeopathology", organized by the U.S. National Academy of Sciences—National Research Council, will be held in Washington on January 14. Further information can be obtained from the U.S. National Academy of Sciences—National Research Council, 2101 Constitution Avenue, Washington D.C. 20418.

The fifth summer research institute of the Australian Mathematical Society will be held at the Australian National University, Canberra, during January 11 - February 19. Further information can be obtained from the secretary of the Institute, J. S. Sandiford, School of Mathematics, University of New South Wales, Kensington, New South Wales.

The fifth seminar of "Electrochemistry" will be held at the Central Electrochemical Research Institute, Karaikudi, during January 27–30. The programme will include technical sessions on: electrode kinetics, electrochemical equilibria and electroanalysis; electro-organic and -inorganic products; electrothermics and electrometallurgy; batteries; electrodeposition and metal finishing; corrosion; miscellaneous. Further information can be obtained from Dr. M. A. V. Devanathan, Central Electrochemical Research Institute, Karaikudi 3.

Corrigendum. In the communication by Prof. J. L. R. Candela *et al.* entitled "Effect of Glucose on Insulin Secretion *in vitro* by Rabbit Pancreas pre-incubated with β-Hydroxybutyrate" (*Nature*, 203, 758; 1964) lines 16 and 17 should read "... Krebs–Henseleit buffer containing β-hydroxybutyrate 1×10^{-2} M . . .".

Corrigendum. In the article entitled "Distribution of Particle Size in Dust" (*Nature*, 203, 1057; 1964), equation (3) should read:

$$p(D) = (\gamma - 1)\, D^{-\gamma} / D_S^{1-\gamma} - D_L^{1-\gamma}$$

Equation (4) should read:

$$P(D) = (D_S^{1-\gamma} - D^{1-\gamma}) / (D_S^{1-\gamma} - D_L^{1-\gamma})$$

and equation (5) should read:

$$\frac{\mathrm{d}P(D)}{\mathrm{d}D} = (\gamma - 1) D^{-\gamma} / (D_S^{1-\gamma} - D_L^{1-\gamma})$$

Erratum. In the review of the book *Classification and Human Evolution*, edited by Sherwood L. Washburn (*Nature*, December 5, p. 951), the heading of the chapter by G. A. Harrison and J. S. Weiner was unfortunately printed as "Some Considerations in the Formulation of Theories of Human Physiology"; for 'Physiology' read 'Phylogeny'.

U.S. INSTITUTE FOR BIOMEDICAL RESEARCH

AN Institute for Biomedical Research is to be established by the American Medical Association Education and Research Foundation and will be officially opened on July 1, 1965. Laboratory and animal research facilities for the Institute will be located in a new addition to the American Medical Association headquarters building in Chicago, now under construction.

A committee has been set up under the chairmanship of Prof. Maurice B. Visscher, chairman of the Department of Physiology of the University of Minnesota Medical School, to advise the Board of the American Association Education and Research Foundation on the qualifications of prospective members of the Institute's scientific staff and to recommend specific applications of policies.

Other members of the committee are Prof. William H. Feldman, chief of laboratory research in pulmonary diseases for the Veterans Administration, Washington, D.C.; Prof. Chauncey D. Leake, Department of Pharmacology, University of California School of Medicine, San Francisco; Prof. Donald D. Van Slyke, member emeritus of the Rockefeller Institute, of Brookhaven National Laboratory, Upton, New York; Prof. Henry Eyring, dean of the University of Utah Graduate School, Salt Lake City, and president-elect of the American Association for the Advancement of Science.

The purposes and policies of the Institute are delineated as follows:

(1) "To provide appropriate personnel, facilities, and conditions, conducive to obtaining significant, basic biomedical information which eventually may be applied to promoting the good health of people.

(2) "The personnel, nominated by the Committee of Scientific Advisors, will include biomedical scientists of the best possible stature or promise with such secretarial and technical assistance as may be appropriate to their respective activities, and with such Post-doctoral Fellows as may be attracted by the individual investigators in relation to their facilities and scientific interests.

(3) "Initial laboratory facilities will include 30,000 square feet of space to be set up and equipped on the recommendations of the scientific personnel and the Committee of Scientific Advisors, together with appropriate quarters and care for experimental animals. Extensive library facilities will be available through the headquarters organization of the American Medical Association.

(4) "Every possible effort will be made to establish such conditions in the Institute as will be stimulating for basic biomedical investigation in accordance with the highest scientific standards and ideals. The organizational policies of the American Medical Association provide liberal financial security and perquisites. Responsible freedom in research and publication is assured. The Institute is expected to maintain the best possible intellectual environment for supporting investigation into fundamental biomedical scientific problems."

C.S.I.R.O. PHYSICS IN AUSTRALIA

THE Divisions of Applied Physics and of Physics of the Commonwealth Scientific and Industrial Research Organization, Australia, are situated at Sydney and form the National Standards Laboratory. The Applied Physics Division is responsible for the establishment and maintenance of mechanical standards of measurement of length, mass and time, and associated measurements, and of electrical standards of measurement. The Division of Physics has similar responsibility for standards in heat, light, viscometry and hygrometry. The annual reports of the Divisions for 1962–63, together with those of the Divisions of Tribophysics and of Meteorological Physics situated at Melbourne have recently been issued*.

The work done in the Division of Applied Physics on the reproducibility of the orange-red radiation of krypton-86 as the primary standard of length, and on other secondary standards, was reported at the 1962 meeting in Paris of the advisory committee on the definition of the metre. A new version of the Fabry–Perot scanning interferometer in use in the division is being designed. A precise quartz-scale and photoelectric microscope for rapid measurement of changes of plate separation to within one order of interference and up to 500 mm are to be incorporated. Alterations are being made to the 1-m line standard comparator. The 0·1-in.-wide thin soft-metal strip to be used in the determination of the gyromagnetic ratio of the proton has been measured and an accuracy of 8×10^{-6} in. achieved in the measurement of the thickness. Steady progress has been made on the construction of the equipment for the absolute determination of gravity by the rise-and-fall method. An accurate bolometer bridge has been developed for the measurement of power at radio and microwave frequencies, and work on magnetic viscosity has been extended by the provision of equipment for the measurement of both loss and permeability as a function of either time or frequency at temperatures up to the Curie temperature. In connexion with the 210-ft. radio telescope at Parkes, New South Wales, a detailed study has been made of the vibration modes of telescope structures.

In the Division of Physics results have been obtained which indicate that the freezing-points of pure tin (231·912° C) and pure cadmium (321·032° C) are worthy of consideration as reference points for platinum resistance thermometry on the International Practical Temperature Scale. There is a continuous demand for consultations on techniques of temperature measurement, and inspections of laboratories on behalf of the National Association of Testing Authorities for the purpose of registration in the field of heat and temperature measurement have continued. Additional qualified laboratories are still needed. The measurement of the thermal conductivity of unirradiated and irradiated BeO at low temperatures, the specific heat of silver below 4° K, and the linear expansion of alkali-halide crystals, germanium and silicon and anisotropic metals at temperatures below 20° K, form part of the solid-state physics research activities of the division. There are facilities for a wide range of precision optical measurements, particularly for interferometry and the

* Commonwealth Scientific and Industrial Research Organization. Annual Report of the Division of Applied Physics, 1962–63. Pp. vi+45. Annual Report of the Division of Physics, 1962–63. Pp. v+28. Annual Report of the Division of Meteorological Physics, 1962–63. Pp. ii+20. Annual Report of the Division of Tribophysics, 1962–63. Pp. i+18. (Commonwealth Scientific and Industrial Research Organization: Sydney and Melbourne, 1963.).

assessment of optical quality. Two-beam interferometers are used for the measurement of the transfer functions of optical systems, and a modified Michelson interferometer, in which the mirror movement is controlled by the application of a uniformly increasing voltage to barium titanate piezoelectric supports, is used for interference spectroscopy. A new technique is being developed for the measurement of solar magnetic fields in which a series of four Fabry–Perot interferometers are used as a tunable monochromater with a 1/50-Å pass band, and the data processed rapidly by an adaptation of television techniques. The Division of Tribophysics is concerned with fundamental investigations in the physics and chemistry of surfaces of solids and in metal physics. The behaviour of solid materials depends to a large extent on defects in the atomic arrangement in the crystals, and strength and ductility in particular depend critically on the imperfections. Point defects in plastically deformed metals and in quenched metals, and the dislocation rearrangements and recovery which occur after deformation, have been determined by the correlation of the results of measurement of many different physical properties. The effect of plastic deformation on the Hall coefficient of copper has been measured. Polycrystalline films of silver have been produced by evaporation on a mica substrate at pressures of the order of 10^{-8} torr and the investigation of damage produced in gold crystals by bombardment with ions of the inert gases has been completed. A thin film of silicon monoxide on an aluminium reflector is a selective surface which emits and absorbs radiation between 8 and 13μ only. This corresponds to one of the several infra-red windows of the atmosphere, and thus the film, which radiates more heat than it absorbs, could be used to form the surface of a refrigerator which requires no supply of power. Patents for such a refrigerator have been granted by Australia and the United States.

The report of the Division of Meteorological Physics deals with investigations under the headings of dynamic meteorology, general micrometeorology, and agricultural meteorology and evaporation. The study of radiative flux divergence in the lowest 15 m of the Earth's atmosphere during clear nights has been continued, and previous results confirmed. A new fast and accurate method for the measurement of radiative heat exchange of human subjects has been developed. The equipment used consists of two balanced net radiometers, which face each other at the same level on opposite sides of the subject and which move at a constant speed in a helical path. Each complete scan, taking about 1 min, sweeps out a vertical cylindrical surface enclosing the subject. Detailed investigations of radioactive fall-out using improved apparatus have been carried out, and the resumption of atomic testing in the Pacific during 1962 provided an opportunity to re-examine features of the fall-out observed following the 1958 tests. On the average, debris from tests at the equator is detected in Melbourne about 11 weeks after release. Information on the structure and lateral extent of rain systems is being obtained by a 10-cm surveillance radar, and a 3-cm wind-finding radar is to be installed.

KINETICS OF PYROLYTIC REACTIONS

UNDER the auspices of the Chemical Institute of Canada a symposium on the kinetics of decompositions and isomerizations was held at the University of Ottawa during September 9–11. There had been no symposium on this topic for a considerable time, and there was lively discussion of a number of questions, including isomerizations of ring compounds, the stability of radicals, over-all mechanisms for inhibited and uninhibited decompositions, and surface effects. It was revealed that a number of major problems are still far from solution, and many specific proposals for future work were put forward.

Several papers dealt with the mechanism of the gas-phase isomerizations of small ring compounds, which in most cases appear to be largely homogeneous and elementary. H. M. Frey (University of Southampton) described six types of thermal gas-phase reactions involving substituted cyclopropanes; these include geometrical and structural isomerizations and ring expansions, and all appear to be unimolecular. Similar conclusions were drawn by W. D. Walters, A. F. Pataracchia and P. C. Ropoli (University of Rochester) in the case of substituted *cyclo*butanes; they studied the reactions in their fall-off regions and compared the Arrhenius parameters.

J. P. Chesick (Haverford College) and M. L. Halberstedt (National Bureau of Standards) described results on the pyrolysis of ethyl*cyclo*propane that could be satisfactorily interpreted in terms of the Marcus quantum modification of the Rice–Ramsperger–Kassel theory of unimolecular reactions.

S. W. Benson (Stanford Research Institute) and P. S. Nangia (University of Southern California) reviewed the kinetic evidence on the decompositions of a number of small-ring compounds. Two extreme modes of isomerization have been proposed for the *cyclo*propane ring compounds: (*a*) cleavage of one C—C bond to form a biradical; (*b*) H migration followed by C—C bond rupture. Similarly, two modes of reaction have been considered in *cyclo*butane studies: (*a*) the biradical mechanism; (*b*) simultaneous cleavage of two C—C bonds to yield the two product molecules. It was argued by Benson and Nangia, and generally agreed, that the evidence favours the biradical mechanism. The reaction path for a group of compounds with activation energy much lower than the usual values for ring isomerization was shown to be consistent with the biradical mechanism if the radical formed is stabilized appreciably by allylic resonance. The value of the resonance energy of the allyl radical was suggested to be about 12 kcal/mole, somewhat lower than previously estimated. Benson and Nangia also proposed that in certain reactions of unsaturated molecules there is the formation of intimate ion-pairs before the biradical configuration is reached. S. G. Cohen and C. Steel (Brandeis University) showed that their results on certain bicyclic hydrocarbons are largely consistent with the biradical mechanism, but suggested a concerted mechanism in which H transfer does contribute slightly to the C—C bond splitting.

The decomposition of ethylene oxide, on the other hand, proceeds by a complicated free-radical mechanism, and O. O. Bernardini and E. A. Cherniak (Carleton University) described results which lead to conclusions about the details of the mechanism.

A completely new approach to the study of unimolecular reactions was described in a paper by I. P. Fisher, J. B. Homer, B. Roberts and F. P. Lossing (National Research Council, Ottawa). A new type of flow reactor, for use with a mass spectrometer, has been constructed, and preliminary results on a number of decompositions were presented. The rate constants measured were in the range 50–5,000 sec^{-1} and were for the most part consistent with those obtained from more conventional investigations on reactions the rate constants of which are of the order of 10^{-3} sec^{-1}. Evidence was obtained for a falling off of the first-order rate coefficients at high temperatures; some discrepancies between the results and the Kassel theory were noted.

The stability and reactivity of free radicals were discussed by P. Gray (University of Leeds) on the basis of the iso-electronic principle and of thermochemistry; reliable data on radical reactions have now accumulated to the point where correlation of structure and reactivity can provide insight into the detailed pattern of radical reactivity. M. Szwarc (State University of New York, Syracuse) considered theoretical and experimental aspects of the decompositions of substances such as metal alkyls, where there may be simultaneous rupture of two bonds if the radical produced by the breaking of one bond is thermodynamically unstable.

The free-radical chain mechanisms for the decomposition of ethane and acetaldehyde were discussed with much vigour, but many unsolved features of these problems remain. Considerable discussion was devoted to the kinetic order of the combination of methyl radicals under various conditions of pressure and temperature, and of the decomposition of the ethyl radical into C_2H_4 and a hydrogen atom. M. H. Back, M. Eusuf and K. J. Laidler (University of Ottawa) reviewed the evidence from various sources and showed that some of it appears contradictory. A. S. Gordon (U.S. Naval Ordnance Test Station, China Lake) described new results on the ethane pyrolysis that favour a mechanism due to Quinn, according to which the ethane dissociation is first-order and the ethyl radical decomposition rate varies with the square root of the pressure of foreign gas; surface effects are, however, important and the rate of diffusion may play a significant part in the over-all mechanism.

M. C. Lin and M. H. Back (University of Ottawa) presented results on the rates of the methane and butane productions in the ethane pyrolysis that were also consistent with Quinn's mechanism. In discussion it was, however, pointed out that there are some difficulties and that further work is necessary on this important reaction. C. P. Quinn (University of Cambridge) described work on the propylene-inhibited decomposition of ethane that indicates that the propylene and the ethane are decomposing simultaneously, by two mutually interacting chain processes, the allyl radicals playing an important role in the inhibition. A paper by M. Niclause, R. Martin, A. Combes and M. Dzierzynski (Université de Nancy) on the pyrolysis of propane and of isopentane emphasized the important accelerating effect of very small traces of oxygen on the reaction rate, and the fact that in some cases the effect of surface is very much less when the reaction proceeds in the absence of oxygen.

Two papers were concerned with the pyrolysis of acetaldehyde. A. B. Trenwith (University of Newcastle upon Tyne) described a study of the formation of minor products of the reaction. He found that acetone was produced more rapidly than ethane and concluded that the main chain-termination step is $CH_3 + CH_3CO \rightarrow CH_3COCH_3$; other interpretations were also suggested, and there is still no agreement on the over-all mechanism of this reaction. D. G. Milne and O. K. Rice (University of North Carolina) described experiments on the decompositions of mixtures of acetaldehyde and azomethane, and proposed mechanisms involving mutually interacting chain processes.

A somewhat different aspect of pyrolysis reactions was described in a paper by F. S. Rowland, E. K. C. Lee, F. Schmidt-Bleek and Y. N. Tang (University of Kansas), who caused high-energy tritium atoms to replace hydrogen atoms in a wide variety of molecules, and examined by radioactive techniques the decompositions of the highly energetic molecules produced in this way. They concluded that the decomposition mechanisms are surprisingly like those deduced on the basis of more conventional investigations.

Azomethane and diazomethane both decompose by free-radical mechanisms. W. Forst (Université de Laval) described results on the azomethane decomposition that presented difficulties of interpretation; the methane production, for example, he found to be 3/2 order and this seems to be incompatible with the high activation energy. A paper by W. J. Dunning and C. McCain (University of Bristol) described work on the thermal decomposition of diazomethane in the presence of hydrogen; the results are interpreted in terms of a mechanism in which methylene forms vibrationally excited methane which afterwards decomposes into a methyl radical. B. G. Gowenlock and R. M. Haynes (University of Birmingham) proposed a mechanism for their results on the pyrolysis of acetaldazine, $CH_3CH=N-N=CHCH_3$.

Reactions involving alkoxyl radicals and nitric oxide were the subject of a paper by E. A. Arden, L. Phillips and R. Shaw (Ministry of Aviation, Waltham Abbey), who suggested mechanisms for the formation of N_2, NO_2 and N_2O in such systems.

A paper by S. J. W. Price and M. C. Jacko (University of Windsor) dealt with the decompositions of certain metal alkyls, use being made of a flow system. Breaks in the Arrhenius plots were taken to give evidence with regard to whether the two bonds were broken simultaneously.

Three papers at the symposium were concerned with the pyrolysis of alkyl halides. K. A. Holbrook (University of Hull) described an examination of the role of surface in chloride pyrolyses, and showed that different methods of producing a carbon deposit on the surface led to different kinetic behaviour; electron-spin-resonance investigations on some surfaces lead to conclusions about the presence of free radicals. J. L. Holmes and G. Choudhary (University of Ottawa) described recent work on the pyrolysis of alkyl iodides, and proposed reaction mechanisms to explain the kinetic results. M. R. Bridge and A. Maccoll (University College, London) showed that their results on the effect of *p*-halogen substituents on the pyrolysis of α-phenyl ethyl chlorides were consistent with the view that an ionic type of activated complex is involved. Discussion of the halide pyrolyses was centred about two main problems: the elementary nature of the process and the uncertain role of surface. For some halides the evidence for decomposition by molecular elimination of hydrogen halide appears convincing, but for others the interpretation is doubtful. Many of the customary tests for chain reactions, such as the addition of inhibitors, may have little effect on the over-all rates, and decisive tests have generally not yet been made. Similarly, satisfactory tests for surface effects have usually not been made, and it was emphasized that if initiation and termination are both surface reactions the changing of the surface/volume ratio may have no effect on over-all rates. More convincing evidence would be provided by investigations involving changes in the chemical nature of the surface, as well as its area, and investigations of the elementary reactions that are believed to occur.

Inhibition in pyrolysis mechanisms was discussed at an informal session on the final afternoon. It seems to be generally agreed that the effect of inhibitors is frequently to generate new chain processes. This is a feature of mechanisms proposed by Laidler, Wojciechowski *et al.*, but their suggested chain-ending steps, postulated to explain the over-all kinetic behaviour, were the object of criticism. The alternative proposal of Pratt and Norrish, who emphasize the role of the decomposition of oximes formed as intermediates when nitric oxide is present, was also debated vigorously. It became clear that the matter can only be elucidated by experimental studies of the kinetics of the formation of the minor products of the decompositions, including those products formed from the inhibitor itself.

Constantly throughout the symposium it became apparent that there are many points where there are serious discrepancies as to the facts, as well as many differences of opinion and interpretation. By bringing these matters into sharp focus the symposium will undoubtedly have a significant effect on future work in this field.

K. J. Laidler

UNIVERSITY APPOINTMENTS BOARDS IN BRITAIN

IN 1961, at the suggestion of the University Grants Committee and with the approval of the Committee of Vice-Chancellors and Principals, Nuffield College agreed to undertake and finance an enquiry into the scope, purpose, constitution and organization of university appointments boards, and Lord Heyworth agreed to supervise the enquiry with the assistance of a steering committee.

To a large extent Lord Heyworth, in coming to his conclusions and in framing his recommendations, has relied on the results of surveys carried out of the control, composition, finance and activities of appointments boards through a questionnaire to vice-chancellors, a review of the present and projected work of appointments boards, based on papers written by the secretaries of the boards, and on surveys of fact and opinion relating to the use and utility of the boards among students, recent graduates and employers. This is pointed out by Lord Heyworth in the report of his enquiry which has now been published *.

The report sets out, in successive chapters, the need for appointments boards and considerations of organization, finance and staff, before discussing the employers of graduates, the students searching for a job, appointments services at work, and the future of appointments services. In a later chapter the cost of future work is reviewed, and finally it is emphasized that appointments boards represent a joint responsibility of academic staff, students and employers.

Appointments services have been overtaken by the influx of students and also by the increase in the number of employers of graduates. Invariably they suffer from a shortage of appointments officers and of clerical staff, as well as of accommodation and of excessive concentration of work in the spring term. As a result, the services vary from fairly adequate to frankly rudimentary. The report maintains that, if standards are to be put right and kept right, efforts should be made to see that the ratio of appointments officers to students available for employment should not rise far above 1 : 100; as the number of students increases so the resulting demand for clerical staff and accommodation should be met. It recommends that certain functions now performed separately by various services should be performed centrally for the benefit of all, thus lightening the burden of labour and reducing the cost. This refers particularly to certain information services, and especially those connected with a register of employers. To bring to a proper state of efficiency the services now offered by appointments boards would require an increase in the total expenditure of all boards of upwards of 40 per cent on the average for 1961–62 of £14·2 a head. This would bring the sum *per capita* to £25, which should be set against the £1,500 - £3,000 a year which to-day the education of a university student costs the State (depending on his subject). The lowest figure of fixed expenditure for running an appointments service is likely to be about £5,000 a year, but with growth of the service economies of scale might reduce somewhat the expenditure *per capita*.

The overriding purpose of the report in making these recommendations regarding appointments boards is better service both to students and to employers so that students may develop their abilities to the full and make their fullest contribution to the national life. To this end the closest co-operation is essential between the boards and their staffs and the other parties mainly concerned, namely, the academic staff of the universities, the students and the employers.

PRIMARY EDUCATION IN BRITAIN

THE National Union of Teachers has published, under the title *First Things First**, a memorandum of evidence submitted to the Central Advisory Council for Education (England), under the chairmanship of Lady Plowden, which presents the results of extensive consultation with teachers serving in the primary schools. It is based on replies to a questionnaire which was circulated among Union members. The questionnaire, which had been drawn up by the Plowden Committee, covered the stages of primary education, the transition from primary to secondary education, the work of the primary schools, their size and organization, teachers and their training, handicapped children and the relation of home, school and community.

Points of special interest in the memorandum include a request to the Council to investigate the possible development of the present services available to mothers through the child welfare clinics, so that advice is available not only on the nutritional and medical aspects of child nurture, but also on those quasi-educational functions which only the mother can render to the child at this stage of growth. No claim is made that the evidence presented on the transition from primary to secondary education represents the opinion of all primary-school teachers, but the lack of general agreement disclosed by the questionnaire reveals that many quite definite patterns of thought exist.

The pamphlet observes that, if the value of the comprehensive school is to be properly tested, certain necessary conditions must be established: first, the intake must be genuinely comprehensive with no subtraction of children regarded as having higher ability, and, secondly, its buildings must be designed or satisfactorily adapted for their purpose. In very few areas have both these conditions been fulfilled. The memorandum stresses the need to create adaptable minds well furnished with the basic concepts which underlie modern social organization and its technology. So far as the primary school is concerned, the problem is one of using its free and informal methodology in a curricula context that is directed towards the new aims of the secondary school.

The memorandum welcomes the many experiments now being carried out into ways in which mathematical and scientific ideas can be developed inside the framework of primary method. The use of primary teachers without professional training or teaching in the primary school is not simply a question of the best internal organization. Highly trained teachers are the key to success in solving the problems affecting the balance between internal freedom and the responsibility of the school to society. The memorandum argues that, if the social role of the primary school is to be continued to be regarded as the great

* National Union of Teachers. *First Things First:* A Memorandum of Evidence Submitted to the Central Advisory Committee for Education (England) under the chairmanship of Lady Plowden. (An inquiry into primary education in all its aspects and the transition to secondary education.) Pp. 44. (London: National Union of Teachers, 1964.) 2*s*. 6*d*.

provider of equal opportunity for all children, it is imperative that the great majority of children should have opportunities of enjoying the benefits that highly skilled and, therefore, highly trained teachers can confer.

The National Union of Teachers fears most that, although the evidence for the maximum provision of educational opportunity at the earliest stages may be accepted, the form of school organization indicated may be rejected because of the anxiety that now exists about the supply of teachers in the immediate future. The Union urges that no purely economic considerations should be allowed to lead to legislation that will permanently warp the present primary-school system—a system which for many reasons is educationally desirable.

INTRODUCED SPECIES OF AMPHIBIA AND REPTILIA IN MAINLAND BRITAIN

THE native fauna of mainland Britain is small compared with that of continental Europe. In the last glaciation of the Ice Age, the great ice sheets stretched almost as far south as the Thames, and only with their recession could the fauna of warmer climates spread back from the southern part of Europe. At that time the area which is now the English Channel was occupied by dry land, so that movement across it was relatively easy. With the invasion of the sea and the opening of the Channel Gap some 5,000 years ago, those species which had already entered the country were separated from those which had not yet reached so far north. Since then, any changes in the British fauna can only be due to extinction of some, and further passage across the sea by others, whether aided or unaided by man. In the case of amphibia and reptiles, such passage (apart from the occasional turtles) has invariably been aided.

The surviving species of amphibia and reptiles which reached Britain unaided comprise only two toads, one frog, three newts, three snakes and three lizards. Species used in attempts at naturalization far outnumber these, yet success has been infrequent. The motives for the enlargements of alien species appear to have been varied, ranging between curiosity to see if they could establish themselves, or the liberation of captive specimens, the discarding of unwanted pets or even the escape of captive specimens. Casual escapes are unlikely to have taken place in such numbers as to form breeding populations except in the case of common pets such as tortoises. In the *British Journal of Herpetology* (3; June 1964), J. F. D. Frazer, of the Nature Conservancy, has classified the introduced species as follows: (*a*) Species which cannot survive Britain's normal conditions of weather, terrain and soil. These must be presumed to include the Madeiran wall lizard, the eyed lizard, the European wall lizard *L. campestos* (at least under conditions where it has been liberated hitherto), and the platanna, *Xenopus laevis*. (*b*) Species which can survive under normal conditions, but which are killed in exceptionally severe winters, for example, Ewing's tree-frog. (*c*) Species of which the adults can survive even under severe conditions, but where breeding never takes place, or only in exceptional summers. These include the snapper and other American terrapins, the Greek tortoise, the geckos, the green lizard and the bullfrog. The fire-bellied toad is also included here. (*d*) Species of which the eggs can normally hatch or the young be born, but cannot reach adulthood. These may possibly include the green tree-frog in some parts of Britain. (*e*) Species which have not been introduced originally in sufficient numbers to produce success. The painted frog and fire salamander come into this group, which also probably includes a number of introductions of green tree-frogs, where not enough have been liberated in one place to allow sufficient females to survive until the next breeding season. There is the further complication that this species is imported in large numbers when taken at the breeding ponds, so that there will be far fewer females than males, and a whole consignment of 500 may contain only one or two females. At best, an unsorted batch of 100 liberated would only be expected to contain about ten females. (*f*) Species which apparently succeed in establishing themselves, but then go into decline. The major example of this is the edible frog, assuming that it was never native to the fen district. Its final decline can be associated with the destruction of its habitat, and it may be significant that its disappearance in East Anglia coincided with changes in land management and with increasing use and pollution of the waterways, while the decline in the traditional cutting and use of reed was associated with a great silting-up process. It may be that the fading fortunes of such a species are due to its changing environment becoming unsuitable for it. (*g*) Finally, the species which seem to have colonized the land successfully have either been deposited in a suitable habitat, as in the case of the marsh frog, wall lizard (*L. muralis* and *L. nigriventris*) and some successful colonies of green tree-frog; or, as with the alpine newt, midwife and yellow-bellied toads, have been fairly inconspicuous species which are not particularly specialized in their requirements. In this connexion it is interesting to contrast the breeding failures of the fire-bellied toad, which lives in and around shallow water in lowland terrain, with its congener, the yellow-bellied toad. This is more a creature of mountain streams, and it must have found the Devon hills to its liking.

SPECULATION ON THE ORIGIN AND NON-SYMMETRY OF TWO THIN LAYERS *D″* AND *F* EMBRACING THE LIQUID CORE INSIDE THE EARTH

By Dr. V. S. TUMAN

Stanford Research Institute, Menlo Park, California

IN general the Earth is considered to be formed of a thin crustal layer covering a fairly thick mantle which embraces its core. Bullen[1] utilized seismic data to form a model of Earth subdivided into eight regions. The crustal layers form region *A*, which has an average of 33 km thickness. Mantle, forming the regions *B*, *C* and *D′*, extends to a depth of 2,700 km and is followed by a region *D″*, which extends from 2,700 to 2,900 km. The core is subdivided into three regions, *E*, *F* and *G*.

The two layers *D″* and *F* embrace the outer core, layer *E*, which is generally considered to be liquid because it does not transmit the shear waves[2]. The nature and

composition of D'' and F, however, are subject to considerable conjecture[3–11].

Pfann *et al.*, in 1957 (ref. 12), and Bardeen *et al.*, in 1958 (ref. 13), published the results of some experiments on the Peltier effect, the principle of which will be utilized to speculate on the origin of D'' and F layers. Both Pfann and Bardeen show that Peltier cooling between a metal and its melt gives rise to a further growth of the solid phase, while the reverse process, Peltier heating, will increase the volume of the melt. It is necessary to estimate conditions which would give rise to Peltier heating and cooling at the core–mantle boundary. These results could easily be extended to cover the boundary conditions at the solid and the liquid cores.

Theoretical estimation of the Peltier coefficients. The basic ideas of Peltier effect as applied to solid and its melt were developed by Reiss[12]. These ideas are utilized to estimate the Peltier coefficients, which will indicate whether melting or freezing occurs at the core–mantle boundary due to electric currents.

If the D'' layer and the F layer are due to Peltier precipitation and melting, the velocity of the interface must be larger than zero:

$$v = \frac{\frac{PI}{J} + K_c\tau_c - K_m\tau_m}{H} > 0$$

where K is the thermal conductivity, τ the thermal gradient, I the current density, and H the heat of fusion.

From this we obtain for:

$$I = 10^{-3}\ \text{amp/cm}^2 - P > 3{\cdot}9 \times 10^{-3}\ \text{V, hot zone}$$

$$I = 10^{-3}\ \text{amp/cm}^2 - P > 12{\cdot}3 \times 10^{-3}\ \text{V, cold zone}$$

$$I = 10^{-6}\ \text{amp/cm}^2 - P > 8{\cdot}0\ \text{V, hot zone}$$

$$I = 10^{-6}\ \text{amp/cm}^2 - P > 8{\cdot}0\ \text{V, cold zone}$$

The Peltier coefficients of solid and its melt measured by Pfann and Bardeen are Bi = −0·013 V, Cd and Zn = 0·003 V, and Ge = 0·200 V. In general the Peltier coefficients of semiconductors are considerably larger than the coefficients of conductors. It is therefore feasible that the Peltier coefficient of the mantle (a semiconductor) against the molten iron is quite large. The Peltier range $-8 > P > 12{\cdot}3 \times 10^{-3}$ V, as calculated for boundary conditions, is within the range of the Peltier coefficients observed under laboratory conditions.

Pressure and temperature conditions prevailing at the core–mantle boundary are considerably different from those under which Pfann's and Bardeen's data were obtained. Bridgman[14] has shown that, in general, the value of the Peltier coefficient increases with the increase of pressure. The behaviour of the Peltier coefficient of iron as a function of temperature is fairly complicated, and it is not possible at present to predict its behaviour at very high temperatures. Therefore, if a current density $10^{-3} > I > 10^{-6}$ amp/cm^2 flows through the boundaries, it is reasonable to presume that Peltier heating or precipitation would occur.

Speculations on the origin of the D'' and F layers. Let us speculate that some of the electric current loops circulating in the molten core are in the vicinity of the core–mantle boundary, and that these currents partially penetrate into the mantle. At the boundary, depending on the direction of the electric currents, either a Peltier cooling or a Peltier heating will occur. If the conditions are suitable, on one side of the electric current loop the Peltier heating will raise the temperature of this zone above the melting-point of the mantle material, producing a melt of mantle. This melt, being of lighter silicate material, will float as a sludge over the material of the core at the core–mantle boundary. If the silicon metal is quite abundant, 10–20 atomic per cent in the molten core as Ringwood[9] has suggested, then it will indeed react with the iron oxide of the mantle melt giving rise to silica. The floating melt of the mantle, which is now enriched in silica at the expense of losing some iron to the core, will become even lighter than the original mixture. This aggregate of the molten sludge may eventually solidify in the relatively cold zone at the surface of the mantle, or it may remain as an aggregate of molten material in the vicinity of the hot zone.

The other side of the loop, the region at the core–mantle boundary, will be cooled by the Peltier effect. If the cooling continues faster than the rate at which heat is supplied by the floating mantle melt or other agents, then eventually the temperature of this locality may drop to the freezing point of the iron, giving rise to a partial solidification. The iron crystals with their impurities will grow on the solid mantle. If the cohesive forces between these crystals and the solid mantle are strong, so long as the temperature conditions prevail they may form a solid iron layer as a permanent feature of this locality. Runcorn[3] also has postulated the existence of a solid iron layer with varying thickness of up to 10 km. If the freezing-point temperature of the molten core is appreciably below the standard average temperature of the core–mantle boundary, then even a partial solidification of iron would be an unstable condition.

Similarly, the electric current loops, if they exist in the vicinity of the solid–liquid core (the F region), will give rise to partial melting of the solid core at one point, while freezing a portion of the molten core at another point. Such a process will form a series of undulations (hills and valleys) and thus produce a non-spherical boundary.

The coriolis forces due to the rotation of the Earth probably will increase interaction between the core and the mantle in the plane of the equator. Consequently, if the conditions are suitable, the Peltier activity should be maximal in the equatorial belt.

Based on these speculations, D'' layer is composed partially of mantle material (slightly enriched in silica and extruding non-symmetrically into the molten core), and partially of molten core material intruding into the base of the mantle. Bolt recently has suggested that F layer has an intermediate seismic velocity between the two cores[5–7]. An intermediate velocity would be obtained from the path of a ray passing partially through liquid and partially through solid core. According to this model, the two layers D'' and F are not continuous layers but probably have a maximum anomalous thickness in the vicinity of the equatorial belt.

Other geophysical evidence supporting the model. According to Miss Lehmann[15], the seismic data from the record at the epicentral distance of 105°–115° indicate the variation of the depth of the core–mantle boundary and possibly a variation in the constitution of the bordering region. On the basis of *PcP*, *ScS*, *PcS* and *ScP* waves, Vogel[16] has shown that the surface of the outer core is undulated with amplitudes up to 200 km.

Jeffreys[17] has a map of free air gravity anomalies which indicate some broad features of about 20 milligals spread around the Earth in the equatorial belt. I have maintained for a long while that the source of these anomalies can be in the neighbourhood of the core–mantle boundary. Recently published calculations by Egyed[16], which are based on the work of other investigators[18–20], also support this view. The striking similarity between the isopores of vertical magnetic intensity for the years 1942.5. pointed out by Egyed[16] was also observed by me and it was discussed with several colleagues of Stanford University. These magnetic anomalies may be utilized to locate the geometrical position of the major current loop within the molten core interacting with the mantle.

The three independent geophysical observations (seismic, gravity, magnetic) seem to support the model presented in this article.

Concluding remarks. For a current density $10^{-6} < I < 10^{-3}$ amp/cm^2 this mechanism is physically feasible when

the corresponding Peltier coefficient between the mantle and the core is:

$$-8 > P > -12{\cdot}3 \times 10^{-3}\,\mathrm{V}$$

To produce the layer D'' several million years of sustained electric current flow is necessary.

It is likely that the process of melting slightly outbalances the process of freezing; thus we can speculate that a molten sludge of mantle material has accumulated gradually. It follows that the layer D'' is made of non-continuous aggregate of molten sludges which travel with the current cells, which in turn give rise to magnetic secular variations. Such a model predicts a secular westward drift of gravity anomalies. However, if the conditions are such that the process of melting balances the process of freezing, then the layer D'' would represent predominantly a solid layer formed of mantle material enriched in silica. Consequently, the undulations would be a permanent feature of core–mantle boundary. If such undulations are produced by Peltier effect, we must seek the origin of some electric currents which are of more permanent nature and seek another explanation for the similarity between the gravity and the magnetic anomalies.

I thank Profs. G. A. Parks, G. A. Thompson, B. A. Bolt, J. Vergoogen and S. Ward for their advice. I also thank Dr. Francis Everitt and Margaret S. Guthrie for their assistance.

LONG-PERIOD PULSATIONS OF AURORAL-ZONE X-RAYS

By Prof. H. TREFALL and S. L. ULLALAND
Department of Physics, University of Bergen, Norway

During a series of balloon flights from Andenes in northern Norway, several observations were made of nearly periodic intensity variations of bremsstrahlung X-rays, with periods of about 8–10 min. This is approximately equal to the estimated period for the fundamental mode of oscillation of the geomagnetic field, and is also in good agreement with previous observations of long-period geomagnetic pulsations.

Observations of this kind may be of considerable theoretical interest, because of the information they may contain about the processes in the Earth's magnetosphere which accelerate electrons and precipitate them into the atmosphere. In this article we shall not, however, try to suggest or discuss possible acceleration mechanisms, but merely report the observations which have been made, and see how they fit in with other observations of long-period geomagnetic pulsations, and with our present ideas about the magnetic régime in the Earth's immediate neighbourhood.

Precipitation into the atmosphere of electrons with energies of the order of 25–100 keV was recorded through observation of the associated bremsstrahlung. Whereas electrons with such energies are stopped at altitudes of about 100 km, the X-rays produced in the process penetrate down to balloon altitudes of 25–35 km. The balloons were of the now common non-pressurized polyethylene type, which can float for about a day at a nearly constant pressure-level. The size of the balloons was about 4,200 m^3 and they usually floated at atmospheric depths of about 8–10 g/cm^2.

Most balloons carried a standard instrumentation consisting of two Victoreen type 1*B*85 and one type 6306 Geiger–Müller counters, all mounted horizontally and immediately above each other, with the 6306 counter in the middle position. The counting rates of the upper type 1*B*85 counter, of the type 6306 counter, and of the triple coincidence counter telescope formed by all three counters, were recorded. Some balloons carried more complicated systems of counters, with up to 7 counting channels. However, as all the results to be presented in this preliminary note are based on the records from one single unshielded counter channel, there is here no need for any more detailed description of the other detector systems.

Andenes is located at 69·3° N., 16·1° E., and lies very close to the line of maximum auroral activity. Altogether 29 balloons were launched during July 17–September 27, 1963. In spite of several balloon failures X-rays were observed during 17 of these flights. The average levels of solar activity and associated geophysical disturbances were unusually high during this period, considering how close it was to a solar cycle minimum.

Three obvious cases of nearly periodic X-ray intensity variations were observed. These are shown in Figs. 1*a*, 2*a* and 3*a*. It should be noted that the intensity scale is logarithmic in all diagrams, which reduces the heights of the peaks as compared with a linear plot. No associated variations in the counting rate of the counter telescope were observed, proving that the intensity increases above the cosmic-ray background were not caused by particle radiations.

In the first of the three cases here reported (August 5, Fig. 1*a*), the periodic intensity variation seems to be superimposed on a more slowly varying X-ray event, of the type which is often associated with magnetic bays[1]. Examination of magnetograms from the observatory of Tromsø, about 100 km geomagnetically east of Andenes, reveals that a magnetic bay with $\Delta H = -500\gamma$ did indeed occur at the time of this event, even though there was no detailed correspondence between magnetic variations at Tromsø and the X-ray intensity peaks recorded by the balloon-borne detectors.

The event of September 23 (Fig. 2*a*) also occurred in connexion with a strong negative magnetic bay ($\Delta H = -600\gamma$ at Tromsø). In this case there is no indication of a more slowly varying X-ray event on which the pulsations are superimposed, except that one peak, which

* The times given in this figure should be increased by 5 min due to an error in plotting

would have been the third of the series, appears to be missing. Again no detailed correspondence was found between magnetic and X-ray variations.

The third case (September 27, Fig. 3a) resembles the first one in that there again appears to be a superposition of a slowly varying X-ray event and a pulsating one, but at this time only a weak magnetic disturbance was recorded at Tromsø. There had, however, been considerable magnetic activity earlier during the night. This event was the most long-lasting of those here reported, and altogether 8 major peaks occurred between 0250 and 0403 U.T. Unfortunately the high-voltage power supply for the Geiger counters failed at 0407 U.T., and it is not known how long the pulsations continued.

The periods of the three pulsating X-ray events can be determined quite well from the average spacing of consecutive major intensity peaks, but it can be done more accurately by examining the corresponding autocorrelation functions. These have therefore been computed, and are presented in Figs. 1b–3b, corresponding to the events of Figs. 1a–3a. The periods are seen to be approximately 650, 450 and 520 sec, respectively.

Even though no detailed correspondence was found between any of the observed X-ray events and the mag-

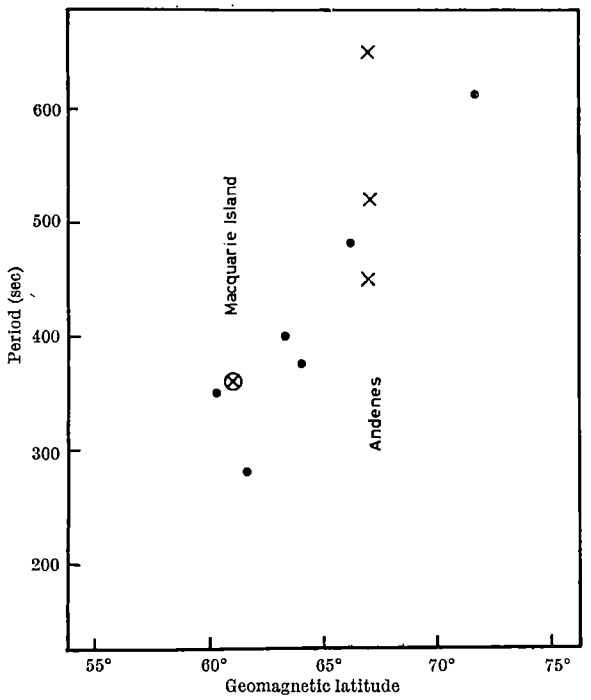

Fig. 4. Periods of geomagnetic pulsations and X-ray events as a function of geomagnetic latitude. Black dots represent periods of geomagnetic pulsations as summarized by Ohl (ref. 2), open crosses represent the X-ray pulsation periods reported in this paper, and the circled cross represents the X-ray event reported by Anger *et al.* (ref. 5)

netic variations recorded at Tromsø, we still think that the observed electron precipitation may have been associated with oscillations of corresponding periods in the Earth's magnetosphere, because of the near equality between the periods of these X-ray intensity variations and those of long-period giant magnetic pulsations.

In Fig. 4 we have plotted the observed periods of such magnetic pulsations against geomagnetic latitude, using data taken from Ohl[2], and the periods of the X-ray intensity variations observed by us, which are seen to be in fair agreement with the periods of geomagnetic pulsations.

Dungey[3] has suggested that geomagnetic micropulsations may be due to hydromagnetic oscillations in the magnetosphere. He showed that the fundamental mode would be an oscillation of the whole of a geomagnetic line of force in outer space, and estimated the corresponding period to be of the order of several minutes for lines of force connecting with the auroral zone. Furthermore, the period would increase rapidly with increasing geomagnetic latitude, because of the increasing length of the geomagnetic lines of force. Jacobs[4] showed that the period of oscillation would also depend on the size of the magnetosphere, and computed theoretical estimates for several different assumed values of the equatorial radius of the magnetosphere. The period would obviously increase with increasing radius, because this would extend the lines of force. For lines of force connecting with the auroral zones, Jacobs found periods between 100 and 1,000 sec, depending on the assumed size of the magnetosphere.

It is therefore interesting to note that of the three X-ray events reported here, that with the shortest period was associated with the highest value of the planetary K_p-index. This was the event of September 23, when the K_p-index for the 3-h interval encompassing the X-ray event was 9^-. The event of September 27, with a period of 520 sec, occurred at a time when K_p was only 3^+, and so also did the event of August 5, which had a period of 650 sec. However, the average K_p-indices for the 24-h intervals preceding these two events were 4 and 3^-, respectively. For the event of September 23, the corresponding 24-h average was 6^+. If the X-ray events discussed here are actually associated with oscillations of magnetic lines of force, this inverse relationship between K_p-index and X-ray pulsation period would be consistent with the expected dependence of the hydromagnetic oscillation period, on the size of the magnetosphere, because the higher the K_p-index the more should the magnetosphere be compressed by the solar wind.

The difference in periods between the events of September 27 and August 5 could, however, also be due to a diurnal variation of the period of oscillation of a magnetic line of force, associated with a diurnal change in the length of such a line. One would expect the length to be a maximum at geomagnetic midnight, when the line of force lies in the tail of the magnetosphere, and a minimum at geomagnetic noon when it lies in the compressed part of the magnetosphere. Now the event of September 27 occurred at about 0600 h local geomagnetic time, whereas the event of August 5 occurred at about 0300 h local geomagnetic time, and this might conceivably explain the difference in periods. The event of September 23, however, occurred at the same local time as the event of September 27, and no diurnal variation can account for the difference in periods between these two events. But these were the cases which were associated with such very different K_p-indices, as mentioned above.

Only two direct observations of long-period pulsating X-ray events have previously been reported. One event was observed by Anger *et al.*[5] during a balloon flight from Macquarie Island, Australia, between 61° and 62° S. geomagnetic latitude. The observed period was about 360 sec, which has also been plotted in Fig. 4 at the appropriate latitude, and is seen to fit in very well with the other observations. This event is the only one so far which has been definitely associated with corresponding geomagnetic pulsations. It occurred at approximately 8 h local geomagnetic time, and the K_p-index at the time was about 5^-. The other previously reported long-period pulsating X-ray event was observed by Evans[6], and was the most nearly periodic of all those so far reported. It had, however, a period of only 100 sec, but was recorded during a balloon flight from College, Alaska, at about 65° N geomagnetic latitude, and therefore definitely falls outside the group of events included in Fig. 4. The event reported by Evans may perhaps be associated with a different mode of oscillation of the geomagnetic field.

The three cases of periodic X-ray events here reported are the most conspicuous among several other cases of long-period (several minutes) pulsating events recorded during our 1963 series of balloon flights from Andenes. A systematic search for such periodicities is now being conducted.

Further investigations will be needed to decide whether the observed events are caused by periodic acceleration of electrons by hydromagnetic waves, or whether magnetic oscillations merely perturb the orbits of electrons already trapped in the radiation belts and thus cause them to enter the atmosphere with nearly periodically varying intensities.

It is also possible that the observed pulsations may be due to a periodic movement of the region of electron precipitation, which should be investigated by means of X-ray recordings performed simultaneously from two different balloons, separated by a suitable distance.

This work was financed mainly by a research grant from the NATO Scientific Committee in Paris, with additional contributions from the Norwegian Council for Technological and Scientific Research, and from the University of Bergen.

COLOUR OF PRECIOUS OPAL

By Dr. J. V. SANDERS
Commonwealth Scientific and Industrial Research Organization, Division of Tribophysics, University of Melbourne

SOME Australian opals are renowned for the glorious displays of colours which they exhibit. They are consequently known as precious opals, and are valued as gem stones.

It is known that the colours from precious opals are spectral and polarized, and it is commonly conceded that they are caused by 'diffraction' rather than 'interference'[1-4]. In 1932 Baier[3] made an extensive optical investigation of these colours, and concluded that they were produced by a lamellar structure. Later, Raman[4] suggested that opals displaying colours were made up of regularly spaced layers of two types of silica with different refractive indices. However, the work recorded here using electron microscopy has shown that, in fact, the colours are caused by diffraction from a regular three-dimensional structure arising from the regular packing of spherical particles of silica, 1500–4000 Å in diameter.

Structure of opals. Precious opals are brittle and easily fractured. When a shadowed replica of a freshly fractured surface is examined in an electron microscope, a regularly spaced array of regularly shaped holes can be seen (Figs. 1, 2 and 3). Replicas of surfaces etched in dilute hydrofluoric acid revealed the amorphous silica spheres of which these opals are composed[5] (Fig. 4). The holes in the fracture surface are presumed to be sections of the voids between the spheres, and although this is not generally obvious from their shapes (such as in Fig. 3) it is reasonably clear in the particular section shown in Fig. 2.

In any opal displaying colours, the spheres are remarkably uniform in size, and they may, therefore, pack regularly. That they do so can be seen in Fig. 4; but it is demonstrated more convincingly by the extensive regularity of the patterns of holes, such as in Fig. 1. Because this regularity appeared on all freshly fractured surfaces of precious opal which have been examined, it may be concluded generally that the voids and spheres lie on a regular three-dimensional lattice. Micrographs suggest that the packing is face-centred cubic, but that it may be faulted and twinned.

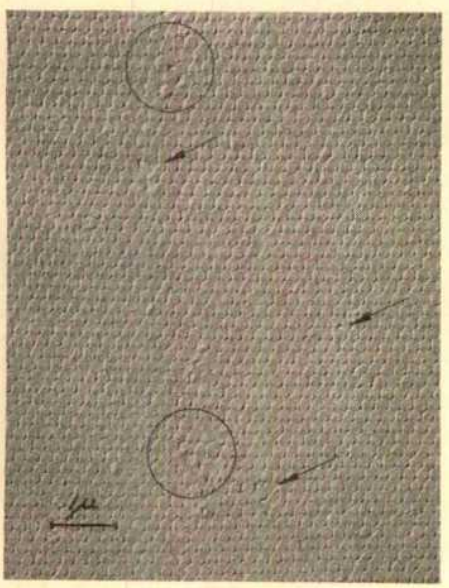

Fig. 1. Shadowed replica (Pt-C 20°) of a freshly fractured surface of an opal from Lightning Ridge (× *c.* 8,700)

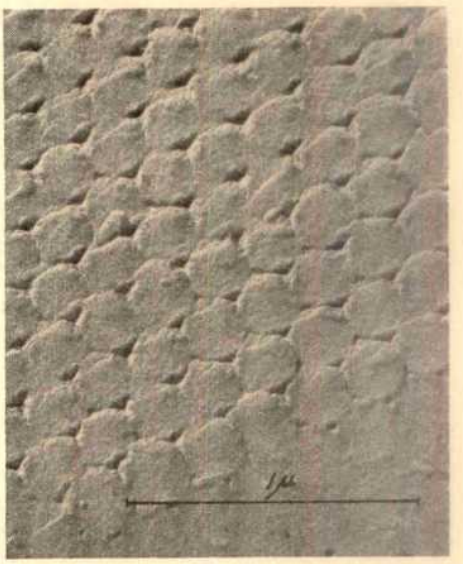

Fig. 2. Section of an area similar to Fig. 1 showing details of the holes (× *c.* 39,000)

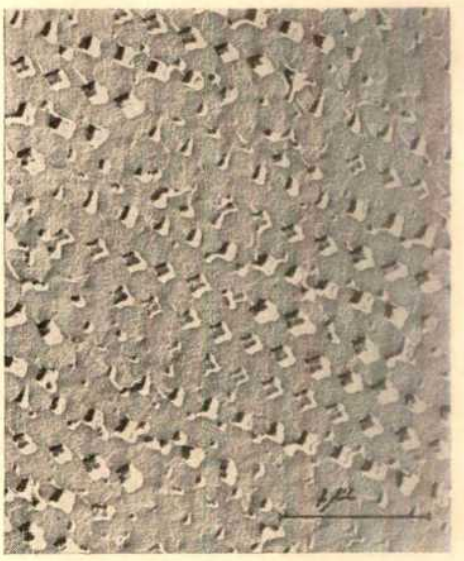

Fig. 3. Alternative section through the lattice of voids showing varying shapes of holes (C replica shadowed with uranium oxide, × *c.* 20,000)

Ideally, the voids between spheres in a close-packed array are either 'tetrahedral' or 'octahedral' and lie on the same lattice as the spheres. However, micrographs (Figs. 2 and 3) show that the holes have non-ideal shapes, and that the smaller tetrahedral voids are commonly missing.

It is considered that the matrix is generally optically transparent but, because the refractive index of silica is relatively high (~1·45), light should be scattered at the surface of the voids. Since the voids are regularly arranged, with a suitable lattice parameter, the whole array should act as a three-dimensional optical diffraction grating. The monochromatic diffracted beams produced by this grating are the colours which can be seen in opals.

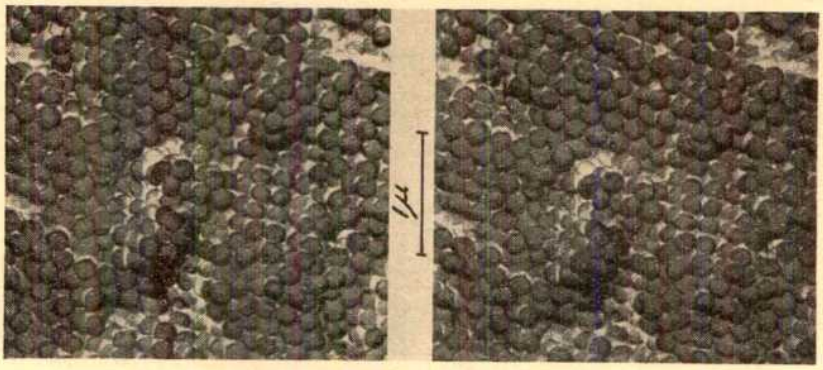

Fig. 4. Heavily etched (30 sec, 10 per cent HF) fracture surface of a coloured opal (Pt-C shadow + C, replica ; stereo pair, × 16,000)

Diffraction by the lattice of voids. The geometry of the diffraction conditions here is very similar to that which occurs in X-ray crystallography, because the wave-length of visible light (0·4–0·8μ) is about the same as the parameter (a_0 = 0·2–0·5μ) of the lattice produced by the spheres. A similar situation has been investigated for 'crystals' of latex spheres[6], and TIV virus[7,8], where it was established that the packing was face centred cubic rather than hexagonally close packed.

The range of colours which can be seen in a given specimen of opal will be determined by two factors. First, the size of the spheres will determine the lattice parameter, and hence the maximum wave-length which can appear. Secondly, the range of colours will be limited by refraction at the surface. In contrast to X-ray diffraction the refractive index is appreciably greater than one, and light rays are bent at the interface so that only a restricted range of Bragg angles is possible within the specimen.

The longest wave-length which can be diffracted by a face-centred-cubic arrangement (λ_{max}) is a beam which can be diffracted back by (111) planes, that is, the Bragg angle, θ, is π/2 and sin θ = 1. This maximum wave-length is related to the sphere diameter (d) and the refractive index (μ = 1·45 for amorphous silica) by:

$$\lambda_{max} = \mu \cdot 2a_0/\sqrt{3} = 2{\cdot}37d$$

for face-centred-cubic packing, when $a_0 = d\sqrt{2}$.

For a plane surface, refraction at the interface restricts the range of colours so that the minimum wave-length (λ_{min}) which can escape after being diffracted is:

$$\lambda_{min} = \lambda_{max}\sqrt{1 - 1/\mu^2} = 0{\cdot}72\ \lambda_{max}$$

Thus, for an opal which can just give red (λ_{max} = 7000 Å), the shortest wave-length which can be seen from it is green (λ_{min} = 5000 Å) if it has a plane surface.

For a given sample, with a fixed sphere diameter (and hence fixed a_0), shorter wave-lengths will appear at smaller Bragg angles. This effect is readily observed by taking an opal, looking at it with the incident light behind one's head, and rotating the opal until the colour of maximum wave-length is observed from a particular area. Movement of the observer about the opal, which is simultaneously rotated but at half the angular velocity, then gives the spectral colours in order of decreasing wave-lengths.

Faulting and twinning will modify slightly the conclusions drawn from a model in which silica spheres pack perfectly in a face-centred-cubic manner.

Verification of the explanation. This explanation of the cause of the colours was confirmed by examining three samples from Coober Pedy. They were: (1) a nearly transparent opal, which exhibited only a violet colour for all angles of incidence and observation; (2) a milky opal which gave only green or blue colours for all angles of incidence and observation; (3) a milky opal which by back diffraction was a homogeneous red for a given orientation of the sample. This colour changed to spectrally shorter wave-lengths as the angle between the observer and incident light was increased.

Replicas of these samples were examined and the spacing between the holes measured on areas selected for the simplicity of orientation. Other similar samples were etched (0·5 min in 10 per cent hydrofluoric acid) and sphere diameters measured from micrographs of shadowed replicas. In the table, these measurements are given together with estimated values for the maximum wave-length observed in the diffracted beams. The difference in the diameters of the spheres is clear from a comparison of Figs. 5*a*, *b* and *c*.

Table 1

Sample	Spacing between holes (Å)	Sphere diam. (Å)	λ_{max} calc. (Å)	λ_{max} obs. (Å)
I	1750	1750	4150	violet, 4000
II	2100	1900–2100*	4500–5000	green, 5000
III	2900	2500–3500*	5900–8300	red, 7000

* This is the scatter from several different samples.

Relationship between appearance and structure. It has now become clear that the play of colours which is so characteristic of precious opals occurs because the diffraction conditions are satisfied at different angles for different wave-lengths, so that, if an opal is viewed in an extended source of white light, the colour of the diffracted beams changes continuously as it is tilted. Areas over which the colour is the same have the same orientation of the lattice of voids. Such patches are like grains in polycrystals and

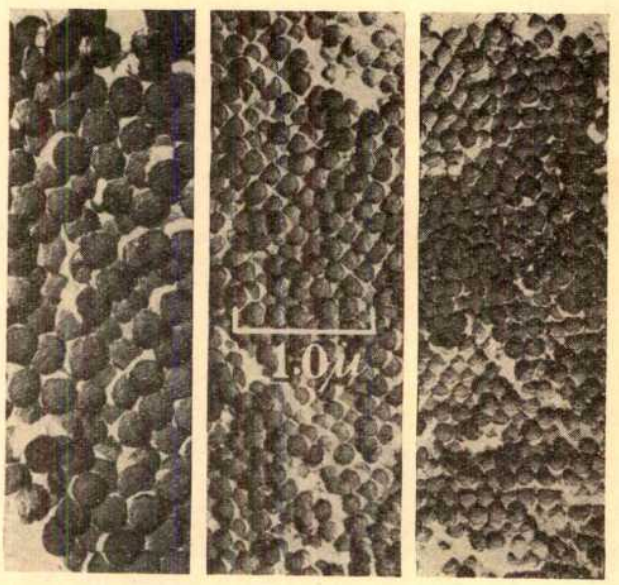

Fig. 5. Heavily etched fracture surfaces of coloured opals *a*, Type I (violet); *b*, type II (green); *c*, type III (red) (Pt-C replica, × 24,000

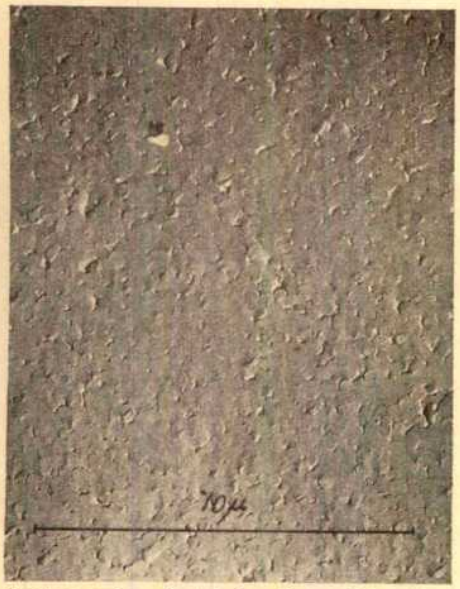

Fig. 6. Fracture surface of potch from Coober Pedy, not exhibiting colours, because there is no regularity of packing of the spheres (Pt-C shadowed replica, × 5,000)

their differences in size and distribution produce variety to the appearance of different samples of opals.

I have already explained how the range of colours depends on the size of the spheres, and their refractive index. This range may be extended to shorter wavelengths if refraction is eliminated by immersing an opal in a fluid of the same or greater refractive index. A dome of transparent plastic on a flat opal would enhance the colour-range in the same way.

When the packing of the spheres is not regular, voids still occur and scatter light; if the irregularities are too great, interference to produce diffracted beams of colour is not possible and the opals look homogeneously milky. Fig. 6 shows that such material (potch) contains voids, but they are irregular; etching confirms that potch are still made from spheres, but that their size and packing is not uniform. Where coloured patches or seams appear in potch, the packing of the spheres must have become regular. Rarely the packing is nearly perfect over a complete specimen and it is, therefore, transparent but diffracting. Thus the most precious opals are made from large spheres regularly packed with little disorder.

It is interesting to note that there are defects in packing of the silica spheres in opals, just as there are in the atomic or molecular packing in crystals. For example, Fig. 1 has been selected because it contains examples of dislocations (in circles) and point defects (arrows).

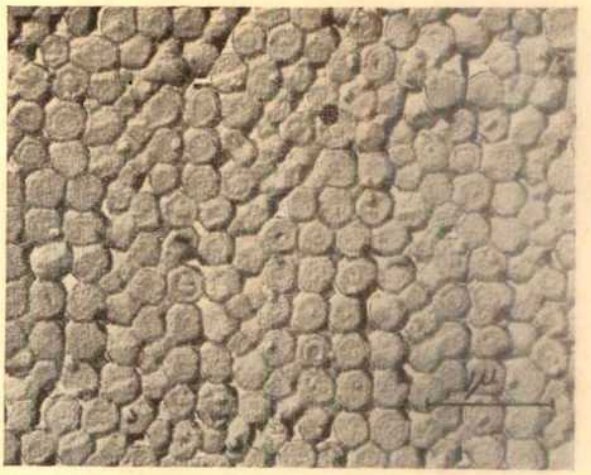

Fig. 7. Lightly etched (10 sec, 10 per cent HF) fracture surface of an opal from Coober Pedy (Pt-C shadowed replica, × 17,000)

Formation of the structure. The size of the holes is generally less than that expected from the close packing of hard spheres. However, etching revealed spheres of apparently almost perfect shape, and consequently it seems unlikely that the size of the voids has been reduced by a homogeneous compression. Furthermore, light etching revealed a detailed structure of sections through the spheres. The central dot and concentric rings (Fig. 7) are consistent with the spheres having grown in suspension by deposition of silica on to a precipitated nucleus. The spheres must then have grown to some size, constant for a given environment, and later packed together, possibly during a filtration process. The way in which the etchant reveals spheres of almost perfect shape suggests that it dissolves silica which has been deposited following the packing of the spheres, and which cements them in position. The extent to which the voids are filled should determine their 'scattering factor', and hence the intensity of the diffracted light. If too much 'cement' were precipitated the voids would become completely filled and the opal would be transparent and not coloured.

I thank Dr. E. R. Segnit, Mr. A. J. Gaskin and Mr. P. J. Darragh for their advice.

PHOTOSENSITIZING PROPERTIES OF DYES AND WHITE PIGMENTS

By Dr. G. S. EGERTON

Department of Polymer and Fibre Science, College of Science and Technology (University of Manchester)

IN his investigations of the photosensitized oxidation of leuco malachite green by acriflavine, Kautsky[1] demonstrated the existence of an active oxidizing entity, but its nature has not been definitely established[1–4]. Evidence that this entity is probably O_2^- is provided by an examination of the similarities of the photosensitizing properties of eosin, acriflavine, the white pigments, zinc oxide, zinc sulphide and titanium dioxide, and various vat dyes. In the presence of oxygen and water the irradiation of these sensitizers by near ultra-violet and visible radiation results in the formation of hydrogen peroxide in solution[5–10]. Neither a dye peroxide[6] nor a metal peroxide[11] is formed. When the water is in the vapour phase the formation of a volatile oxidizing agent some distance from the sensitizer can be demonstrated by its effect on a textile fibre[9,10], or on filter paper containing starch and potassium iodide[10,12]. The sensitizer may be present on a textile fibre[9], or as a solid film which has been pasted with water on a glass plate and dried.

The results in Table 1 were obtained by exposing undyed cotton yarn to sunlight over solid films made with various sensitizers. The marked effect of the peroxide vapour

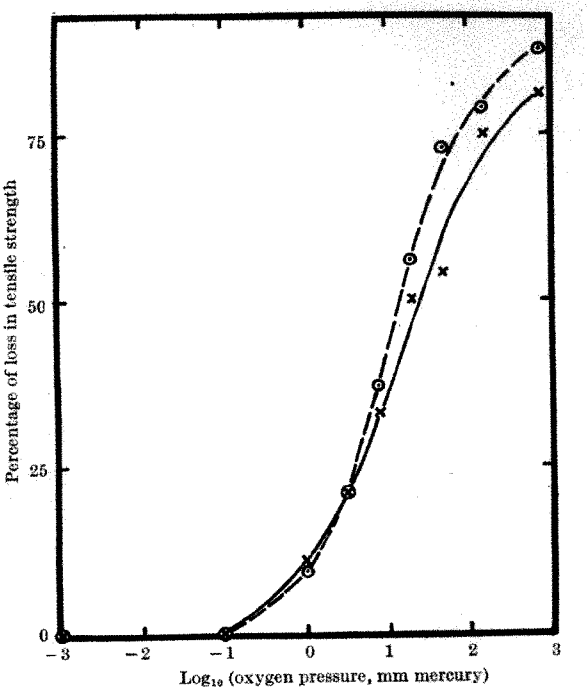

Fig. 1. Nylon yarn dyed with eosin (×) and 'Durindone Orange *R*' (⊙) exposed to sunlight for 24 days at different pressures of dry air and oxygen

produced by these sensitizers in moist air is clear. The degradation of undyed cotton yarn irradiated in the proximity of, but not in contact with, cotton yarn containing any of these sensitizers is increased in the presence of oxygen and water vapour, but it has not been possible to detect the volatile peroxide in the absence of water vapour[9,10]. The presence of oxygen, however, is necessary for the degradation of the dyed and undyed yarns whether or not water vapour is present[13]. These results are in agreement with the observations[7,8,11,14] that the formation of hydrogen peroxide requires the presence of both oxygen and water.

Kautsky[1] rigorously excluded water from his system, so that his entity is different from and actually has a very much shorter life than the volatile peroxide produced in the presence of oxygen and water vapour. Many of his experiments were carried out with the sensitizer and acceptor on separate granules of silica gel, but the sensitizing effect occurred over a much wider range of oxygen pressure when both were adsorbed on the same granule. A similar system would seem to be that in which the sensitizer is on a textile substrate and water vapour is excluded. Many dyes sensitize the degradation of textile fibres in dry oxygen-containing atmospheres by near ultra-violet and visible radiation, and it has been suggested[10] that the degradation is due to attack of the fibre by the oxidizing entity of Kautsky. If this view is correct, as recent results[16] would suggest, then measurement of the degradation of the textile fibre represents a much less sensitive but more quantitative method of assessing the effect of this entity than the oxidation of leuco malachite green. Nylon is particularly sensitive to photosensitized degradation in dry oxygen-containing atmospheres. Some results in which nylon yarns (Du Pont de Nemours, four-fold 45 den. 13 fil., free from delustrant) dyed with eosin and the sensitizing vat dye, 'Durindone Orange *R*', were exposed to sunlight behind glass at various pressures of dry air and in dry oxygen are shown in Fig. 1. The degradation of the dyed nylon is dependent on the oxygen content of the atmosphere and is negligible at low pressures of air. The similarity of the relations between oxygen pressure and degradation suggests that the same mechanism must be involved with both dyes. Similar results to those shown in Fig. 1 have also been obtained with other dyes on nylon, and with dyeings on cotton, silk and viscose rayon yarns. Comparison of the influence of oxygen on the photochemical degradation of undyed nylon containing titanium dioxide (incorporated in manufacture) and nylon free from delustrant but dyed with sensitizing dyes also suggests that the mechanism of degradation in dry oxygen-containing atmospheres is the same for titanium dioxide and dyes.

It is possible to impregnate textile fibres with aqueous suspensions of white pigments, but these treatments have no effect on the photochemical degradation of the textile fibre in dry air, although they may have a very marked effect in moist air[9]. However, if zinc sulphide is precipitated on the textile fibre by double decomposition, then the sensitizer appears to be deposited in sufficiently intimate contact with the textile material to cause sensitized degradation in dry air. This is illustrated in Table 2 for viscose rayon yarn. Similar results have also been obtained with cotton and silk yarns treated in the same manner. In moist air the degradation in the presence of zinc sulphide is the result of attack of the cellulose by the volatile peroxide, which is effective over appreciable distances, and consequently the degradation is not dependent on the state of the sensitizer in the fibre. On the other hand, in dry air photosensitized degradation only occurs when the sensitizer is in intimate contact with the fibre. This is presumably the result of the very limited range of the active oxidizing entity. The results in Table 3 show that the photosensitized oxidation of viscose rayon and cotton yarns by zinc sulphide in intimate contact with these fibres depends on the oxygen content of the atmosphere in exactly the same way as it does with a dyeing of 'Caledon Yellow 5*G*'.

The work described strongly indicates that in the formation of hydrogen peroxide in the presence of oxygen and water, and in the photosensitized degradation of textile fibres in dry and moist air, a common mechanism must

sensitizing dyes and white pigments. s should therefore all be capable of replac- in the Kautsky experiments involving ite green. Moreover, investigations[10] of the cal degradation of nylon dyed with vat dyes hat the active oxidizing entity involved in sky phenomenon must be an intermediate in the on (in the presence of water vapour) of the volatile de. The most conclusive investigations of the anism of the photochemical formation of hydrogen roxide have been made with zinc oxide[11,14,17,18]. The mechanism would seem to involve the capture of a photo-excited electron from the zinc oxide by an adsorbed oxygen molecule[17,18]:

$$\text{Sens} + O_2 \rightarrow \text{Sens}^+ + O_2^- \quad (1)$$

followed by peroxide forming reactions:

$$H^+ + O_2^- \rightarrow HO_2 \quad (2)$$

$$2HO_2 \rightarrow H_2O_2 + O_2 \quad (3)$$

in conformity with the observations that one molecule of oxygen disappears for each molecule of hydrogen peroxide formed[11], and that the oxygen in the peroxide originates entirely from the oxygen gas[17]. These conclusions should apply equally well to zinc sulphide and titanium dioxide. It is to be expected that the method of preparation of these white pigments will influence the removal of electrons from the photoexcited pigment, and so lead to the production of different amounts of hydrogen peroxide[8,14]. An analogous mechanism should apply to the photochemical formation of hydrogen peroxide by dyes, probably:

$$D \text{ (triplet)} + O_2 \rightarrow D^+ + O_2^- \quad (4)$$

a reaction suggested by Uri[19] as the initial step in the photochemical formation of hydrogen peroxide by eosin. The results of Rosenberg and Shombert[2] suggest that with solid adsorbates of acriflavine and fluorescein the excited dye molecule reacts in the triplet state with oxygen; but it is not certain that the triplet state of the dye is always the reactive state[20]. Terenin[21] has obtained some results with solid dye films which indicate that oxygen reduces the photoconductivity of a film of crystal violet by catching the conductivity electrons and is converted in the process into O_2^-.

If these views on the mechanism of the formation of hydrogen peroxide are correct, then the active oxidizing entity involved in the Kautsky phenomenon and the activated oxygen postulated as the initial step in the photochemical degradation of dyed textile fibres[10] must be O_2^-. Little is known about its oxidizing ability; but it is presumably due to hydrogen abstraction from organic molecules to form the ion HO_2^-. It would seem that in the photosensitized degradation of textile fibres by near ultra-violet and visible radiation the fibre is acting in most cases merely as a support medium for the sensitizer during the conversion of oxygen of the air into hydrogen peroxide. During this process the textile fibre is subject to attack by the intermediate (O_2^-) produced during the formation of hydrogen peroxide and by the entities (OH and HO_2) formed during its subsequent thermal or photochemical decomposition. The extent of degradation with any particular sensitizer depends on such factors as temperature[22], humidity of the air, which affects the amount of peroxide produced, and the chemical stability of the textile fibre. In some cases where the formation of the volatile peroxide by the dye seems to be enhanced by a particular substrate it may be that the abstraction by an oxygen molecule of an electron from the excited dye molecule is assisted by the state of the dye in the polymer material in somewhat the same way as the method of preparation influences the photoconducting properties of the white pigments.

These results indicate the importance of the work of Kautsky in the elucidation of reactions involving photo-sensitized oxidation in gas-solid systems.

FINE STRUCTURE OF NATIVE CELLULOSE MICROFIBRILS

By Dr. R. ST. JOHN MANLEY

Physical Chemistry Division, Pulp and Paper Research Institute of Canada, and Department of Chemistry, McGill University, Montreal

THE molecular organization of native cellulose microfibrils has generally been described in terms of the fringed micellar theory, the microfibrils being thus regarded as an assembly of crystalline and amorphous regions. Although this concept has been widely used to explain the behaviour of cellulose fibres, there has recently been increasing evidence[1-3] that it is an over-simplification.

During the past few years investigations have been carried out in this laboratory to elucidate further the molecular morphology of native cellulose fibrils. The purpose of this article is to give a preliminary account of some of the results obtained.

Preparations of microfibrils of ramie, cotton, wood, *Valonia* and bacterial cellulose have been examined in the electron microscope using the negative staining technique[4-6]. Aqueous suspensions of microfibrils were obtained by ultrasonic disintegration. After suitable dilution a drop of suspension was placed on a carbon-coated grid and allowed to dry down. Afterwards a drop of staining agent (1 per cent sodium phosphotungstate or uranyl acetate) was applied to the grid and then withdrawn after a few seconds.

The specimens were examined in a *JEM 6A* electron microscope using the double condenser system and an accelerating voltage of 80 kV. Photographs were taken at an instrumental magnification of 80,000.

Fig. 1 shows a bundle of ramie microfibrils. The individual filaments are 35 Å in diameter and appear to

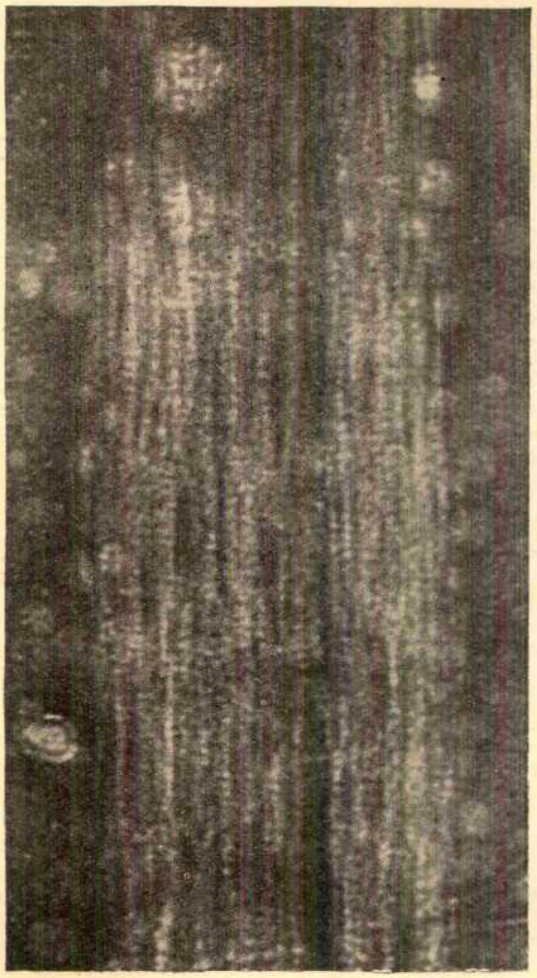

Fig. 1. Electron micrograph showing a bundle of parallel strings of ramie cellulose microfibrils. Negatively stained with sodium phosphotungstate (× 320,000)

have a periodic variation in structure along their length. The effect is rather reminiscent of parallel strings of pearls. Similar observations have been made on cotton, wood, and bacterial cellulose.

The structure of *Valonia* cellulose microfibrils is somewhat more complex. Previous studies in the electron microscope using metal shadowing indicated that these microfibrils are 150–300 Å in diameter[7]. Finer structural elements were not visible. New structural features are revealed by negative staining. Fig. 2 shows a *Valonia* microfibril which contains oval-shaped bodies separated by a short distance along the axis. The diameter of the fibril is 175 Å and the oval-shaped bodies vary in length from 200 to 400 Å. In some cases the microfibrils were wholly or partially devoid of the oval-shaped bodies mentioned above. In these circumstances it became evident that these large *Valonia* microfibrils are in fact composed of smaller filaments 35 Å in diameter. When seen isolated in favourable preparations, they appeared to have the same 'string of pearls' axial organization as seen in the microfibrils of ramie, cotton and wood cellulose.

Attention should be directed to the bent shape of the microfibril in Fig. 2. Normally these microfibrils are more or less straight; but in some cases, presumably as a result of stress on drying down on the substrate, or of ultrasonically induced compression or tension stresses on removal from the cell wall, they become deformed and kink without buckling. It has been repeatedly observed that the angle between the deformed portions is about 120°. At the moment we shall not go deeper into the significance of this observation or the equally interesting question of the nature of the oval s
microfibrils. This will be discussed fu

For the present our main concern is
filaments. Our observations on these stru
confirm and extend the findings of Mühlet
now seems reasonable to propose that these a
structural elements in all native celluloses. A
indicated here, these filaments appear to have a
variation in structure along their axis. At the
stage of our research the possibility that this b
appearance is an electron optical artefact cannot
completely excluded. However, it may still be useful
speculate on its significance, if real. A possible inte
pretation is that the 'beads' are not basic structura
singularities but result from the fact that the microfibril
is composed of a flat ribbon wound in the form of a tight
helix (Fig. 3). If this proposal is accepted, it is pertinent
to enquire how the cellulose chain molecules are disposed
within the coiled microfibril.

From X-ray diffraction investigations it is known that the molecular chain axis is arranged parallel to the length of the microfibrils. Accordingly, if the microfibril is indeed in the form of a tightly wound helix, it follows that there is but one way in which the cellulose molecules can be arranged so as to be parallel to the fibril axis. As seen in Fig. 3*b*, the molecules form flat ribbons by

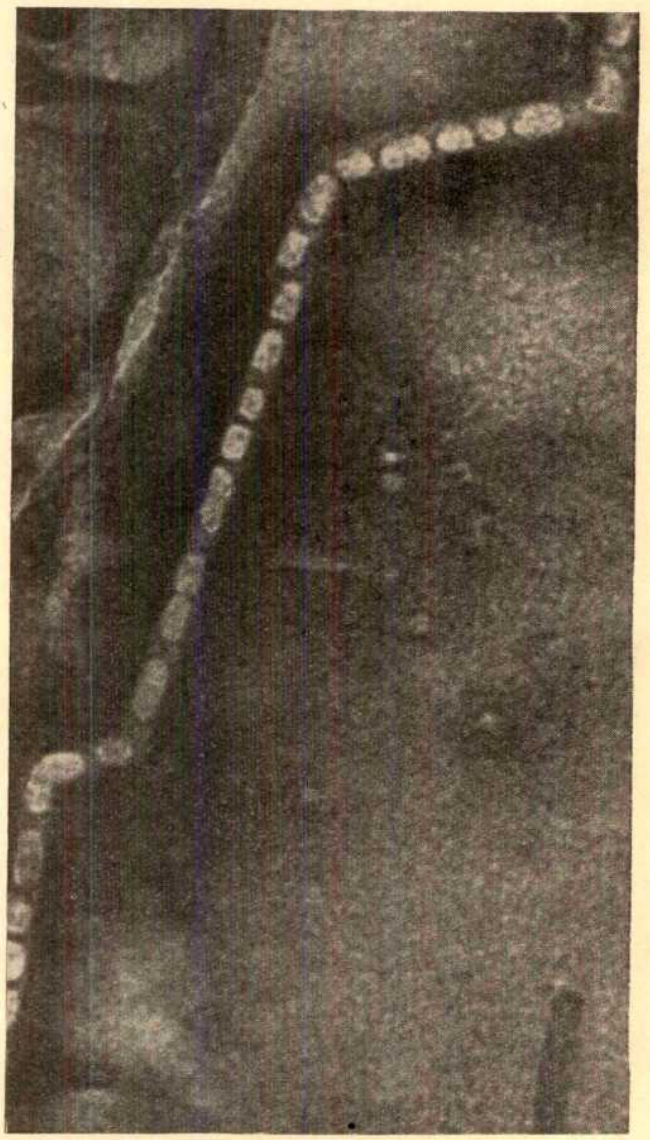

Fig. 2. Electron micrograph of a *Valonia* cellulose microfibril. Negatively stained with sodium phosphotungstate (× 248,000)

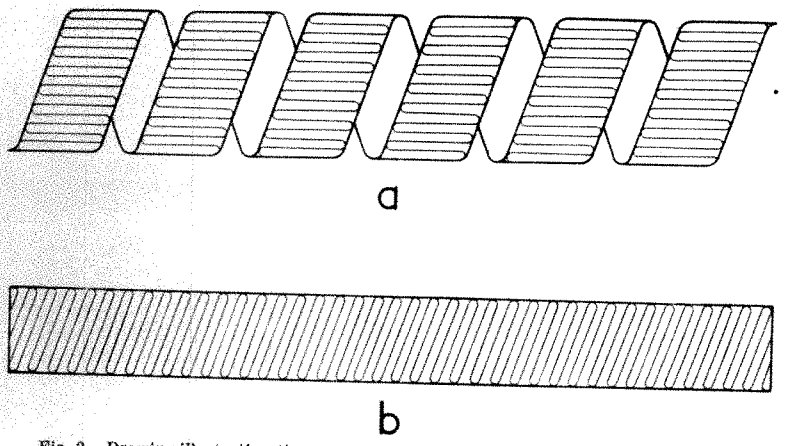

Fig. 3. Drawing illustrating the proposed morphology of a native cellulose microfibril

folding back and forth concertina fashion, and the molecular chain axis is tilted at some preferred angle to the ribbon axis. With the ribbon wound as a helix the molecular chain axis becomes parallel to the fibril axis (Fig. 3*a*).

The question arises whether the cellulose molecule is able to fold in the manner indicated. An examination of Stuart–Briegleb atomic models suggests that it is not only possible, but that only two glucose units would be involved in each fold.

The concept of twisted fibrillar crystals described here is not new. A similar type of helically wound crystalline ribbon has been proposed by Keller[9] for the component fibrils in polymer spherulites. However, in that model the molecules were oriented parallel to the ribbon and therefore nearly normal to the helix axis.

In order to obtain unequivocal evidence for the proposed folded chain configuration I have looked for X-ray low-angle meridional reflexions corresponding to a spacing of about 35 Å. All attempts to observe such a spacing have been unsuccessful. However, the absence of such reflexions is not a proof that the folded structure does not exist. Other methods of proving the structure are at present under investigation.

It is not possible to obtain an accurate measure of the cross-sectional dimensions of the ribbon from the electron micrographs. However, a reasonable estimate would be 10 Å × 35 Å. From the generally accepted Meyer-Misch unit cell dimensions[10] (a = 8·35, b = 10·3, c = 7·9, β = 84°) it is clear that the number of unit cells which could be accommodated within the ribbon cross-section is very small indeed. It seems paradoxical that so small a structure can give rise to discrete crystallographic interferences. Perhaps it would be profitable to consider the X-ray diffraction patterns of cellulose to arise from two different ordered systems, namely, the cellulose chains ordered within the microfibrils and an ordered arrangement of the microfibrils themselves. In this context, it is noteworthy that we have observed a 35 Å equatorial reflexion in low-angle X-ray diagrams of *Valonia* cell walls with the beam oriented parallel to the plane of the wall. This evidently arises from the lateral packing of the microfibrils.

An important characteristic of the model is that the microfibrils do not contain amorphous regions, at least as a separate phase. Each microfibril is really a quasi single crystal, and the diffuseness of the reflexions in the X-ray patterns of cellulose fibres would arise from various types of lattice imperfections; for example, the chain folds and disorder in the mutual arrangement of the microfibrils.

The proposed model has many interesting implications for the interpretation of the properties of cellulose fibres; but as the work is still in progress it would be premature to discuss these matters at the present time.

I thank Dr. S. Inoue for his assistance in obtaining the electron micrographs.

BRAIN MATURATION MEASURED BY ELECTROSHOCK SEIZURES IN RATS AT HIGH ALTITUDE (12,470 ft.; 3,800 m)

By Prof. LOUISE M. HEIM* and Prof. PAOLA S. TIMIRAS

Department of Physiology, University of California, Berkeley, and the White Mountain Research Station, Big Pine, California

INCREASED brain convulsibility, as measured by electrically or chemically induced convulsions, has been reported in adult rats during acclimatization to moderate high altitude[1]. The work recorded here explores the effects of altitude acclimatization on brain maturation in developing rats taken to, or born at, 12,470 ft. (3,800 m). Brain maturation was measured by electroshock techniques in animals: (1) born and maintained at sea-level; (2) born at sea-level and taken to altitude during infancy; (3) born at altitude. Because previous investigations have demonstrated several physiological differences between sea-level and altitude rats[2], other indices of development were also measured in some animals, for example, body growth and weights of organs.

This work was conducted at the University of California, Berkeley, elevation 250 ft.; 76 m (755 mm mercury), and at the Barcroft Laboratory, White Mountain Research Station of the University of California, elevation 12,470 ft.; 3,800 m (480 mm mercury).

An average of 5 litters of Long–Evans rats were placed into each of the following groups: (1) sea-level controls; (2) rats (P) born at sea-level and taken to the Barcroft Laboratory at 4 days of age and maintained there for the entire experimental period; (3) and (4) rats of the first (F_1) and second (F_2) generation born at the Barcroft Laboratory. Both F_1 and F_2 rats as well as sea-level controls were killed at 28 days of age and the weights of total body and of the hypophysis, adrenal glands, thymus, heart and spleen were recorded.

Because in previous experiments brain maturation did not differ in male and female animals younger than 21

days of age[3], animals of either sex were used. Young rats remained with their mothers until the termination of the experiment. Food (the standard rat pellet) and water were given *ad libitum* to the mothers. Conditions of nutrition, caging, temperature and illumination in the animal rooms at sea-level and at altitude were identical.

Electroshock seizures were produced through corneal electrodes as described by Woodbury and Davenport[4]. The stimulus, 50 m.amp alternating current delivered for 0·2 sec duration, activates a series of electronic timers which measure in msec the duration of each of the seizure components. Shocking was begun at 15 days of age. Since mortality is great in young rats shocked daily[3], each group of animals was further subdivided into 2 sub-groups, each sub-group being shocked on alternate days.

The brain of the rat does not reach functional maturity until about 3 weeks of age. During the sequential stages of development the types of responses to electroshock are in chronological succession: hyperkinesis, clonus, fore-limb tonic flexion, hind-limb tonic flexion, fore-limb tonic extension and hind-limb tonic extension[3]. These responses may be associated with biochemical and structural changes in the developing brain[5] and have been used in the young rat to assess brain development under various environmental conditions[3].

The time (days) of appearance of hind-limb extension and fully mature adult seizure pattern in 50 per cent of control and high-altitude rats, calculated by the method of Litchfield and Wilcoxon[6], is presented in Table 1. In high-altitude rats the appearance of hind-limb extension was delayed 2–3 days as compared with the controls. The fully mature seizure pattern appeared 1–2 days later than in controls in rats born at high altitude (F_1 and F_2) but occurred at the same time as the controls in those animals (P) born at sea-level and taken to altitude at 4 days of age. In general the delay in the appearance of adult seizures was proportional to the duration of high-altitude sojourn: it was longest in F_2 rats and shortest in P rats.

When brain maturation is attained at about 22 days of age, animals respond to electrical stimulation with the adult-type maximal electroshock seizure pattern[3]. The sequence of the main components of this pattern is hind-limb tonic flexion, hind-limb tonic extension and whole-body clonus[4]. The durations of the first hind-limb extension and of the adult tonic extension are given in Table 1. Tonic extension was significantly prolonged in all high-altitude rats as compared with controls. The greatest lengthening of this phase occurred in F_2 animals.

The sequential development of seizure patterns correlates with myelination of neuronal pathways involved[5]. Thus, a full tonic–clonic seizure is exhibited by rats in which the nervous system is functionally matured. The results presented here show that the appearance of the adult tonic–clonic seizure is significantly delayed in altitude-born rats. It is suggested that this delay may b due to retardation of brain maturation. Brain glycoge concentration is reduced in adult rats exposed to a altitude of 12,470 ft. for a period of 3–30 days[7]. Exposur to high altitude at an early age might also impair cerebral enzymatic activity because of a diminution of metabolic substrates and thereby delay maturation.

In electroshock seizures the shorter the duration of flexion and/or the longer the duration of extension the more severe is the convulsion[1]. Seizure intensity was markedly increased in adult rats exposed to an altitude of 12,470 ft.[1]. In the experiment described here the prolongation of extension indicates that although brain maturation was delayed, altitude exposure increased the severity of seizures once maturation was achieved.

Retardation in brain development can be related to other signs of altered growth at altitude. Sea-level species which breed at altitude produce litters which are less strong and have less chance for survival than corresponding controls[2]. Inhibition of body growth at altitude for P rats has already been reported[2], and was demonstrated here to be even greater in F_1 and F_2 rats (Table 2). Delayed maturation was further evidenced by significantly decreased hypophysis, adrenal and thymus weights in the animals born at high altitude (Table 2). Other effects of high altitude indicative of altered development were represented by marked cardiac and splenic hypertrophy (Table 2) as part of the cardiovascular compensatory mechanism to hypoxia.

Inasmuch as laboratory conditions for the rat were similar at high altitude and sea-level in terms of nutrition, temperature and illumination, the role of hypoxia and/or hypocapnia in causing neurological changes and other physiological manifestations is now being investigated.

We thank Dr. A. Vernadakis for her advice, and Mr. W. Roche for the care of the rat colony at Barcroft Laboratory.

EFFECT OF CIGARETTE-SMOKE CONDENSATES ON HOMOGRAFTS OF NEONATAL LUNG TISSUE IN MICE

By Dr. JOSEPH A. DiPAOLO

Cytogenetics and Cytology Unit, Office of the Associate Director for Field Studies, National Cancer Institute, Bethesda, Maryland

THE susceptibility of lungs of laboratory animals to the induction of bronchogenic carcinoma by the administration of polycyclic aromatic hydrocarbons, certain metals, radioactive substances and oncogenic viruses has been recently reviewed[1]. It was concluded that the histopathological characteristics of the tumours produced, including the squamous variety, are frequently similar to those observed in man. As yet tumours have not been produced in the lungs of experimental animals by direct inhalation of cigarette-smoke.

The direct effect of cigarette-smoke on lung tissue is still being investigated. Using human fœtal lung in organ culture technique, Lasnitzki[2,3] found that the condensate of cigarette-smoke produced hyperplasia and abnormal mitoses. More recently, Blacklock[4] reported that the direct inoculation with warmed tobacco condensate produced 11 per cent (8/72) malignant tumours of the lung in rats which were allowed to live until death. Hou and Willis[5], using a modification of Horning's[6,7] technique of inducing tumours by the direct application of a carcinogenic compound, found that in rat lung methylcholanthrene pellets produced sarcomas but that tobacco produced only one small papilloma. Since Horning had demonstrated that known carcinogens initiated a high incidence of bronchogenic carcinomas in mouse lung, it was considered important to determine whether lung homografts would respond in a neoplastic manner to cigarette condensate. Unlike most species of laboratory animals, mice develop spontaneous lung tumours. Since genetic susceptibility plays a significant part in the development of pulmonary adenomas in mice, two strains of mice known to have different genetic susceptibilities were used.

New-born strain *A/St* and *DBA/2* mice were used. They were killed with chloroform, and the lungs were removed intact. Each lung was placed in a sterile Petri dish containing a few drops of Ringer's solution. Marginal areas of the lung were removed to increase surface area exposure of the bronchial tissue. The remaining lung was cut into small pieces which would fit into a No. 13 trocar, and partly sliced horizontally with an iridectomy knife. A drop of the material to be tested was applied to each slice with a No. 4 camel-hair brush. The tissue was rolled up with the painted area inside to prevent contact between tar and host tissue. With a No. 13 transplanting trocar the grafts were implanted subcutaneously on either side of the ventral part of the body or in the thigh of the host. Host animals were 6–8 weeks of age at the time of implantation and were of the same sex and inbred strain as the animals from which grafts were taken. Each host animal carried a control graft treated with only a drop of saline.

Graft-bearing animals were not handled for the first two weeks subsequent to the transplant. Afterwards, the graft-bearing area was palpated weekly and recorded as being either firm and well-defined or soft and loose. A few of the host mice were killed as early as 8 weeks after transplant, since obvious growths several times the size of the original graft were noted; however, all remaining mice were killed when the grafts were 6–7 months old. Tumours and other grafts were sectioned, stained with hæmatoxylin and eosin and the diagnosis was confirmed histologically.

The cigarette-smoke condensate was prepared at the Roswell Park Memorial Institute by Dr. F. Bock. One hundred cigarettes of a variety of brands were smoked simultaneously in a manifold type machine having a negative pressure source controlled by an automatic valve[8]. The smoke was collected, condensed, removed with acetone and was condensed at reduced pressure to provide the crude tar, *A*. The *B* tar fraction was obtained by diluting the *A* fraction so that the final concentration of cigarette tar was 15 ml. acetone per carton of cigarettes. The heptane fraction was obtained by dissolving the crude tar in the minimal amount of acetone required and slowly adding eight parts of heptane. The heptane soluble fraction was decanted, condensed, and redissolved in 15 ml. acetone per carton of cigarettes. Solutions were replaced every two weeks.

The numbers of grafts which survived in the treated groups are shown in Table 1. In each series of experiments, 120 lung pieces were obtained from strain *A/St* mice and *DBA/2* mice of either sex and implanted into 30 host mice of the same strain and sex. In all, 180 host mice received 720 grafts of which 90 grafts (12·5 per cent) survived. The proportion of grafts surviving was greatest for tar fraction *A*, which contained the least amount of acetone.

Of the 120 control grafts implanted subcutaneously with saline, 43 (36 per cent) survived, and none developed tumours. Recognizable lung tissue was recovered from both the thigh and the abdominal area.

Successful grafts were firm, and histological examination showed various combinations of complete lung tissue and bronchial elements (Fig. 1). In some instances the alveolar parenchyma was distended while in others it was collapsed. Grafts that failed to grow felt soft when palpated and appeared to be undergoing resorption. The

nuclei were pyknotic, the cytoplasm homogeneous, and areas of necrosis and inflammation were noted.

A positive carcinogenic effect of tar was observed with 23 of the 90 successful grafts (25·6 per cent). Of these neoplasms, 63 per cent were associated with the heptane fraction. With the exception of the pulmonary adenomas, mammary adenocarcinomas and the one possible bronchogenic carcinoma, the tumorous growths are referred to as solid masses, since there is no indication of the tissue of origin. All the tumours were found in strain *A* mice except four adenocarcinomas found in the *DBA* mice, three of which were definitely associated with mammary tissue.

Although primary tumours arose in the grafted area as early as 8 weeks after implantation, the majority took 12 weeks. The one possible bronchogenic carcinoma occurred in lung tissue which had been painted with the heptane fraction. Under low magnification, bronchioles with ciliated epithelium were seen as well as lymphoid tissue and a tumour mass. Under high magnification, this tissue (Fig. 2) appeared to be composed of tumour cells which formed solid sheets of large, polygonal, closely packed cells with abundant cytoplasm, small nuclei and many mitotic figures. Figs. 3 and 4 show examples of remaining tumour masses. A graft from a strain *A* female treated with tar *A* fraction developed a tumour mass composed of coils of stratified squamous epithelium with marked keratinization in some of the coils. This was an adenocarcinoma, probably of mammary gland in origin, with squamous metaplasia. A strain *A* male

Fig. 1. Subcutaneous lung implant treated with heptane tar fraction. Section from strain *A* male shows two bronchioles with ciliated epithelium in middle of loose connective tissue. No tumour noted. (× *c.* 70)

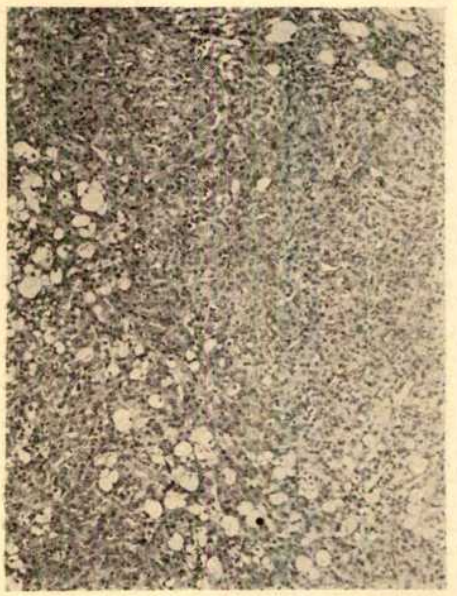

Fig. 2. Subcutaneous lung implant treated with heptane tar fraction. Tumour cells form solid sheets of large, polygonal, closely packed cells with abundant cytoplasm, small nuclei and many mitotic figures. Vacuolated spaces probably represent fat. Compatible with bronchogenic carcinoma. (× *c.* 70)

Fig. 3. Large tumour mass (adenocanthoma) from a strain *A* female which had received lung graft treated with tar *A*. Mass contains glandular elements and pearls of stratified squamous epithelium with marked keratinization in some. Other sections had tubular structures suggesting mammary origin. (× *c.* 70)

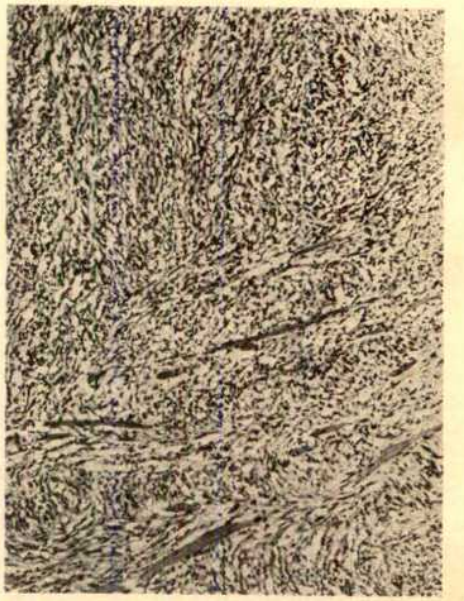

Fig. 4. Subcutaneous tumour mass containing whorls and sheets of small spindle cells. Fibrosarcoma from strain *A* which had received heptane-treated lung. (× *c.* 70)

Table 1. NUMBER OF TAR-TREATED GRAFTS SURVIVING TO SIX MONTHS AND INCIDENCE OF TUMOURS

Treatment	Mouse				Normal		Tumours										
	Strain		Sex				Total tumours	Fibrosarcoma	Bronchogenic carcinoma	Adenoma	Adenocanthoma	Sarcoma	Carcinoma	Adenocarcinoma	Adenocarcinoma, mammary	Undifferentiated tumour	Anaplastic carcinoma mammary
	A/St	*DBA/2*	F	M	Bronchi only	Lung											
Tar *A*	23			23	14	4	5			2			1			1	1
		15	8	7	5	8	2								2		
Tar *B*	11			11	8	1	2						1			1	
		11	2	9	11												
Heptane fraction	18		11	7	4	2	12	1	1		1	1	4	3		1	
		12	8	4	6	4	2							1	1		

bearing a heptane-treated lung graft developed, after 12 weeks, a tumour mass consisting of whorls and sheets of small spindle cells compatible with a fibrosarcoma, possibly a spontaneous tumour (Fig. 4).

Tar application to lung homografts was toxic to the grafts since the permanently implanted rate for such treated grafts was only one-third that of the control group.

As indicated in Table 1, many grafts, particularly those which did not develop tumours, retained their normal lung structures such as mucus-secreting epithelium, ciliated epithelium, and, at times, normally distended alveolar architecture. The majority of the tumour masses, however, could not be identified as having originated from the lung.

Since no tumorous growths were found in any of the control grafts or in the area where these grafts had been implanted in control animals, it must be concluded that the tumour masses were associated with the tobacco tar condensate. Subcutaneous injection of cigarette-smoke condensate or alcohol extracts of the cigarette tobacco have been shown to induce sarcomas at the injection site in the rat[9].

The results obtained in our experiments may be compared to those of Hou and Willis[5] and to those of Horning[6,7]. With the exception of one small intracystic papilloma, Hou and Willis reported negative results with whole tar and with the other tobacco fractions used, while methylcholanthrene elicited occasional neoplastic change in grafted bronchial epithelium. In other cases involving methylcholanthrene, various types of sarcomas developed, probably arising from the connective tissue of both the grafts and the host. Horning found that methylcholanthrene crystals applied to homografts of young adult mouse lung results in a high incidence of adenocarcinomas which were considered bronchogenic. Horning's results with chemical carcinogens and our finding that most of the tumours associated with tobacco tar occurred in strain *A* mice are consistent with the greater susceptibility of certain strains of mice to the development of tumours.

AUTORADIOGRAPHIC EXAMINATION OF THE EFFECTS OF ENRICHED ENVIRONMENT ON THE RATE OF GLIAL MULTIPLICATION IN THE ADULT RAT BRAIN

By PROF. JOSEPH ALTMAN and GOPAL D. DAS

Psychophysiological Laboratory, Massachusetts Institute of Technology, Cambridge, Mass.

THIS pilot experiment was prompted by the results of a recent autoradiographic investigation[1] in which we injected tritiated thymidine into normal adult rats and cats and obtained evidence of the incorporation of this specific DNA precursor by the nuclei of many glia cells. This indicated that glia cells are multiplying in the normal adult brain. Recent electron microscopic and biochemical investigations have suggested that neuroglia form an insulating matrix and a sustaining medium for the neurones embedded in them, and there has been a resurgent interest in the possible role of glia cells in the organization of neural function and behaviour[2]. Is glial multiplication an aspect in the organization and re-organization of brain and behaviour? Since, through their multiplication, neuroglia could modify the electrical and chemical properties of neighbouring neurones, and through their paramount role in myelin formation they could recruit new neurones for newly organized circuits, we undertook to determine if changes occur in the rate of glial multiplication as a consequence of a sustained and radical behavioural manipulation. The procedure utilized in this work was one originally introduced by Hebb[3] in which rats are reared in 'impoverished' and 'enriched' environments, representing different conditions for the development of behaviour. This procedure was shown to affect the subsequent learning ability of animals[4,5] as well as the concentration of cholinesterase in brain structures[6,7] and the size of the cortex[8,9].

Laboratory-bred, normally raised Long–Evans hooded rats were weaned at the age of 23–26 days. From each litter, half of the males were transferred into isolation cages 10 in. deep, 4 in. wide and 6·5 in. high, covered with opaque material on all sides except the bottom. This represented the 'restricted' environment. The other half of the males, and all the females, were put into a large communal cage, 30 in. deep, 45 in. wide and 70 in. high, with a 'Plexiglass' front. This latter cage, which represented the 'enriched' environment, had three levels. The food trays and water bottles were initially placed at the first level which could be reached by the animals by climbing a metal strip 1 in. wide. The food trays and water bottles were gradually shifted from level to level and their position was changed every second or third day, forcing the animals to climb higher and follow varied routes to changing locations of food and water. Later, some of the metal strips forming the passageways were removed and replaced by less easily negotiable chains, then gaps were left across which the animals had to jump. In addition to this regimen, the animals, from the age of 1·5 months, were made to run 5 days every week in a

motor-driven activity wheel 14 in. in diameter, the speed of which was gradually increased from 3 to 8 r.p.m. while the duration of daily running was increased from 15 min to 1 h.

At the age of about 4·5 months 3 restricted and 3 enriched rats, matched as nearly as possible for weight, were injected intraperitoneally on two successive days with 2 mc. of tritiated thymidine (specific activity 6·0 c./mmole, dissolved in 2 ml. of sterile water). After the injections the animals continued to live in their respective environments for 1 week and were then killed by cardiac perfusion with 10 per cent neutral formalin. In a similar manner 3 'restricted' and 3 'enriched' rats were injected with 2·4 mc. of tritiated leucine (specific activity 5·4 c./mmole; dissolved in 2·4 ml. of sterile isotonic saline) and killed after an exchange period of 60 min by cardiac perfusion with neutral formalin. While an attempt was made to match the restricted and enriched animals for weight, the mean body-weight of the 6 enriched rats was 5·2 per cent below the body-weight of the 6 restricted rats. In contrast, the brain-weight of the enriched rats was 9·7 per cent above the brain-weight of the restricted rats ($P < 0·01$). The fixed brains were embedded in 'Paraplast' and 6-μ sections were cut serially. The deparaffinized sections from the brains of the thymidine-injected rats were stained with gallocyanin chromalum and all sections were coated in the dark by the dipping technique with *NTB*-3 nuclear emulsion. The coated slides were exposed for 13 weeks at 5° C and were then developed in the usual manner. In this article we shall deal essentially with autoradiographic results obtained from the animals injected with tritiated thymidine, with occasional references to findings with the animals injected with tritiated leucine.

The glial nuclei incorporating tritiated thymidine are easily recognizable by the overlying reduced silver grains (Fig. 1). Such 'labelled' glial cells were identified in varied numbers in all the animals, both in white and grey matter, over the entire neuraxis. However, the frequency of labelled glial cells varied over different regions. For quantitative evaluation, the number of labelled glial cells in circular areas 310μ in diameter was counted at a high magnification (500 times) over the entire surface of several brain structures. To obtain sufficient samples, some structures with identifiable components were counted as single entities (for example, 'dorsal thalamus'). Table 1 gives a summary of the results, showing a significant increase in the number of labelled glial cells over the neocortex in the group of enriched rats. A trend of statistically non-significant increase was also obtained in the rhinencephalon, thalamus, inferior colliculus and medulla, with the exception of the hypothalamus in which the number of labelled cells in the enriched and impoverished animals was identical. Table 2 gives a breakdown for the neocortex at different coronal levels, indicating greater increases in some regions than others. But in all instances the increases were higher in the neocortex than in other structures.

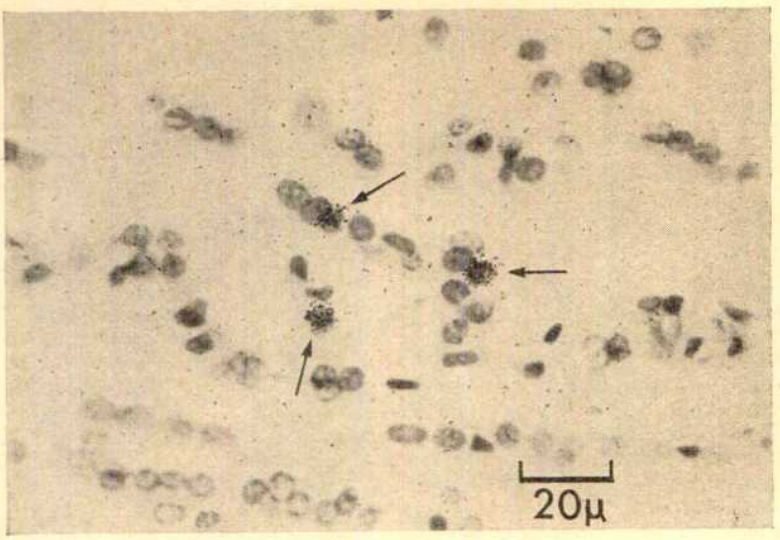

Fig. 1. Photomicrograph of a gallocyanin and chromalum stained autoradiogram. Arrows point to labelled glia cells in cortical radiation

In addition to an increase in labelled cells per unit area in the neocortex of enriched rats, areal measurements at 160 times magnification gave significant increases in the size of the cortex of enriched animals at all coronal levels examined (Table 3). This increase in the area of the cortex should further contribute to the absolute increase in the number of labelled glia cells. A comparison of the mean total number of labelled cells at different cortical levels is given in Table 4, which indicates a pooled increase of 75 per cent in the total number of labelled glia cells in the sampled sections of the cortex of enriched rats. The number of labelled cells given in Table 4 represents cells preparing for multiplication at the time of injection (and possibly some of their daughter cells) in an average section of the cortex with a nominal thickness of 1–2μ, which is the range of penetration of the electrons emitted by tritium into the emulsion.

We did not attempt a breakdown of the type of neuroglia cells labelled in the cortex, but it was clear from our results that the great increase in labelled cells in the cortex of enriched animals was to be attributed largely to cells situated in the cortical radiation and corpus callosum rather than the grey matter of the cortex. This observation can be interpreted in at least two ways. First, the increased labelling of cells in these fibrous structures may be a regional phenomenon, perhaps reflecting the proliferation of interfascicular glia cells. An alternative interpretation is that the labelled cells in these tracts are undifferentiated cells which are in the process of migration to undetermined cortical sites. This latter possibility was suggested by earlier histological observations of the presence of an ependymal and sub-ependymal germinal matrix in adult rats in the dorsal and lateral walls of the lateral ventricle[11–13], a finding which was confirmed more recently in colchicine-treated animals[14] and in animals injected with tritiated thymidine[15–18]. According to recent autoradiographic evidence from our laboratory (unpublished), the cells of the sub-ependymal layer of the dorsal

and lateral walls of the anterior lateral ventricle are in a rapid process of turnover in young as well as adult rats. At this site the majority of labelled cells in the adult rat disappear after survival for 2 weeks, whence the labelled cells migrate to as yet undetermined sites along the cortical radiation over the wall of the caudate nucleus. Since the animals in this investigation were permitted to survive for 1 week only after injection of tritiated thymidine, the cells produced along the wall of the lateral ventricle may have been caught in their migration along the cortical tracts. If this hypothesis were correct, we could expect a more rapid depletion of labelled cells in the wall of the lateral ventricle in the enriched than in the impoverished animals. Accordingly, we counted the number of labelled cells in the dorso-lateral wall of the lateral ventricle and in the adjacent portion of the cortical radiation which is characteristically studded with dark-staining nuclei (the presumed path of migration). Supporting the hypothesis, we found a smaller proportion of labelled cells in this germinal region in the enriched animals (15·6 per cent) than in the impoverished animals (21·1 per cent), though the difference between the two groups was not statistically significant.

It could be argued that the uptake of labelled thymidine by a larger number of glia cells in the cortex of enriched animals is not due to a higher rate of cellular proliferation but to an increased availability of exogenous chemicals as a consequence of changed circulation or a modified 'blood-brain barrier'. This possibility is counter-indicated by our finding of an absence of increased uptake of tritiated leucine in the brain of enriched animals. Indeed, paralleling the findings of Krech *et al.*[6,7], preliminary evaluation of our results indicates a decline in 'protein metabolism' per unit area in the cortex of enriched rats. Our findings also confirm the report of these investigators, based on much larger samples, of an increase in the weight and the volume of the cortex in the enriched animals. The increased addition of new glia cells to the cortex might be one of the variables contributing to this increase in cortical volume, but other variables (such as increased outgrowth of neuronal processes and increased vascularization) may also be involved.

In summary, this pilot investigation brought evidence of the addition of a higher number of newly formed glia cells to the cortex of rats reared in an enriched environment than in rats reared in an impoverished milieu. A trend of less pronounced increase in labelled glia cells was also observed in most of the subcortical structures sampled, the hypothalamus excepted. Since the hypothalamus is the only structure in the series which is practically devoid of corticopetal and corticofugal fibres, the increase in the other subcortical structures may be attributed to cortical fibres passing through them. As a final point we stress that these results cannot be interpreted as representing morphological changes produced by learning. The raising of animals in an enriched environment represents a complex of behavioural and related variables, and increased opportunity for learning and for the storage of experience may or may not have been among the factors that produced the demonstrated change.

This investigation was supported by the U.S. Atomic Energy Commission.

EFFECTS OF HYPOTHALAMIC STIMULATION ON THE ERYTHROPOIETIC RESPONSE IN THE RHESUS MONKEY

By Prof. E. A. MIRAND and Dr. J. T. GRACE, jun.
Roswell Park Memorial Institute, New York State Department of Health, Buffalo

ALTHOUGH there are some differences of opinion as to the location of the hypothalamic areas regulating pituitary hormone secretion, there is general agreement that the output of adrenocorticotrophic (ACTH), thyrotrophic (TSH) and gonadotrophic hormone is regulated via the hypothalamus. The investigations of Reichlin[1] and of Franz *et al.*[2] have provided evidence that the hypothalamus also regulates growth hormone (GH) secretion. Both electrical stimulation and injury of the hypothalamic complex have been reported to induce increases in the number of erythrocytes and reticulocytes[3–5]. More recent investigations by Halvorsen[6–8] and Siep[9] indicated that the hypothalamus may participate in the regulation of erythropoiesis in rabbits. They noted that electrical

stimulation of the hypothalamus increased the reticulocyte level and red cell mass in some of their rabbits. Plasma from such rabbits increased erythrocyte uptake of iron-59 and reticulocytes when injected into starved mice[6].

Piliero *et al.*[10] investigated the erythropoietic response to long-term hypoxia in rats with hypothalamic lesions and found no difference between the operated and sham-operated animals.

In the light of the findings of the foregoing investigators, we became interested in examining the effect of electrical stimulation of the hypothalamus on erythropoietin production in rhesus monkeys.

Eleven female rhesus monkeys, in normal health and nutrition, provided the pooled plasma specimens used, and plasmas from these animals were assayed for erythropoietin levels in polycythæmic mice. The monkeys were non-uræmic (plasma urea nitrogen values < 25 mg per cent) and non-anæmic (venous hæmatocrits > 38 vol. per cent).

Two nickel–chromium wire electrodes were stereotaxically inserted into the left side of the brain of a rhesus monkey under general anæsthesia. These electrodes were fully insulated, except at the tip, and were 0·09 mm in diameter. The electrodes were designed to operate as bipolar electrodes. Forty-eight hours following electrode insertion, the two electrodes (designated anterior and posterior) were stimulated on a BRS (Behavioural Research Systems) constant current stimulator. The following currents were individually used on each electrode: *Anterior electrode*, a current varying from 0·6 to 0·7 m.amp was administered for a 300 msec duration every 30 sec for 3-h periods on six days; *Posterior electrode*, a current varying from 0·28 to 0·30 m.amp was administered for 300 msec duration every 30 sec for 3-h periods on four days.

Blood was collected before and throughout stimulation; however, care was taken to prevent monkeys from becoming anæmic.

Following completion of the stimulation of the brain, a lesion was burned in each area to assist in later anatomical localization of the electrode position. For the anterior lead a 6-m.amp current was administered. A 4-m.amp current was used for the posterior lead.

The electrodes were designed to be inserted anteriorly into the area preopticus and posteriorly slightly anterior to the mammillary body of the hypothalamus. The electrodes were fixed utilizing the stereotaxic localization co-ordinates of Snyder and Lee[11], and a correction factor for the skull cap based on animal body-weight charts was used. Two weeks after the creation of the electrode lesions, killing was accomplished under pentothal anæsthesia. The brain was fixed and perfused in buffered formalin solutions. Serial sections and multiple staining procedures were then used to locate the lesion.

Five-week-old Swiss *Ha/ICR* mice 30–35 g in weight were used for assay animals. Each assay animal was injected intraperitoneally with a total of 2·5 c.c. of washed red blood cells from the same strain to induce polycythæmia; the hæmatocrits had to be in the 75–85 per cent range before using them as assay animals. The animals were checked for polycythæmia prior to receiving the pooled rhesus monkey plasmas to assure the cessation of erythropoietin production and, therefore, erythropoiesis[12,13]. Each polycythæmic mouse received 0·5 c.c. of rhesus plasma subcutaneously on days 1, 2 and 3, and on the fourth day 0·5 μc of iron-59 in 0·2 ml. of saline was injected intravenously. On the fifth day a 24-h uptake of iron-59 in the blood was determined[14,15].

Table 1. Erythropoietin Assay of Pooled Plasmas from Rhesus Monkeys with Hypothalamic Stimulation versus Controls

Mean ± *S.D.*	0·59 ± 0·10	0·65 ± 0·40	6·77 ± 7·7	10·99 ± 4·8

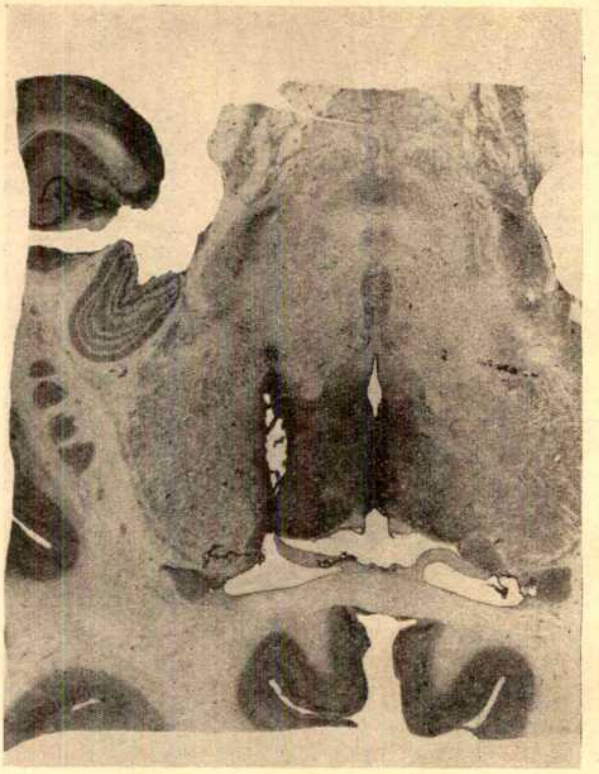

Fig. 1. Histopathological section of the midbrain of monkey *C*–728. Area of posterior electrode lesion is located near the peripeduncular nucleus of the midbrain and the lateral geniculate body

The results summarized in Table 1 show that plasmas from rhesus monkeys responding to hypothalamic stimulation have an increased erythrocyte uptake of iron-59. In runs Nos. 1 and 2 the 24-h iron-59 uptakes by the blood were 10–15 times greater than control uptakes. Hæmatocrit levels of the polycythæmic mice at the conclusion of the experiment ranged from 64 to 71 per cent and the average was 68 per cent.

Plasma collected from rhesus monkeys with hypothalamic lesions and assayed in polycythæmic mice did not show any increases in the 24-h iron-59 uptakes by the blood. The uptakes were comparable with control values.

Serial sections in the electrode stimulation investigation confirmed that two areas were affected; the two were simultaneously stimulated. The anterior electrode was placed in the supraoptic nucleus of the hypothalamus. The posterior electrode (Fig. 1) was located near the peripeduncular nucleus of the midbrain and the lateral geniculate body.

This work demonstrates that high levels of plasma erythropoietin can be obtained from rhesus monkeys subjected to hypothalamic stimulation. Although hypothalamic stimulation increases erythropoietin production, the way in which this is accomplished is unknown. Perhaps oxygen tension is registered in the hypothalamic area and target organs for erythropoietin production are stimulated via the hypothalamus by neurohormones.

The functional significance of the two areas of the brain in terms of the precise localization of a focus for erythropoietin stimulation must remain unsettled from these investigations; however, it is suspected, in view of other findings, that the anterior lead located precisely in

the supraoptic nucleus of the hypothalamus is the more likely site of the two chosen[8].

Piliero *et al.*[10] found no difference in the erythropoietic response of rats with hypothalamic lesions and normal rats; however, he did not stimulate the hypothalamic areas since he used voltage only to produce lesions which can be located histologically. Therefore, our results reaffirm that it is the stimulation, not the placement of the electrodes or the creation of hypothalamic lesions, that determines the absence or presence of an erythropoietic response. For these reasons in this investigation, we felt it was important that animals be allowed to recover from the effects of the electrode insertion and anæsthesia for two days before stimulation began.

It might be worth while to point out that Halvorsen[6–8] obtained an erythropoietic response in rabbits when he stimulated his electrodes bilaterally inserted into the hypothalamus, whereas in this investigation we placed electrodes on only one side and stimulated these individually at a later time.

We thank Edwin Dywinski, Andre Bulba, Helen Fox, Joyce Jividen, Ruth Deckert and A. G. Mirand for their assistance.

METHYLHISTAMINE AND HISTAMINE IN THE URINE OF WOMEN DURING THE ELABORATION OF ŒSTROGEN

By Prof. JACK PETER GREEN, Dr. DAVID H. FRAM* and Prof. NATHAN KASE

Departments of Pharmacology and Obstetrics and Gynecology, Yale University School of Medicine, New Haven, Conn.

MOST of the histamine in man is catabolized[1–4] either to methylhistamine (that is, 1-methyl-4-(β-aminoethyl) imidazole), a reaction catalysed by histamine-*N*-methyl transferase, or to imidazoleacetic acid, a reaction initiated by diamine oxidase (Fig. 1). The major route is methylation[1], and the methylating enzyme[5], in contrast with diamine oxidase[1,2,6], has no known substrate except histamine. Methylhistamine is oxidatively deaminated by monoamine oxidase[1] to methylimidazoleacetic acid which, along with imidazoleacetic acid, is the major metabolite found in urine[1]. Although no methods are available to measure methylimidazoleacetic acid or imidazoleacetic acid, the availability[7] of a method to measure methylhistamine provided an opportunity to gain some insight into the rate of methylation of endogenous histamine.

Measurements[7] on the urine of laboratory personnel showed that the ratio, methylhistamine to histamine (on a weight basis), ranged from 6 to 15, with no difference between sexes. Surprisingly, the urine of two women showed ratios of 3·2 and 1·3, both due to a relative increase in urinary histamine. The woman with a ratio of 3·2 was five months pregnant; the other woman was taking a preparation containing œstradiol and hydroxyprogesterone, and, after withdrawal of these hormones, the ratio rose to 7 (ref. 7). These observations prompted us to examine urine to see if the ratio of methylhistamine to histamine was correlated with the excretion of œstrogens. To this end, these amines and œstrogen were measured in the urine of hypogonadotrophic hypogonadal women during the elaboration of œstrogen by previously inactive ovarian follicles stimulated by exogenous gonadotrophin[8]. Measurements were also made on two normally menstruating women, one of whom has a history of infertility.

Patient 1, who had never been pregnant, developed total amenorrhœa of three years duration following progressive oligomenorrhœa. During the course of amenorrhœa, slight but persistent bilateral lactation was noted. The only significant findings on physical examination were lactation, a profoundly atrophic uterus, and small firm ovaries. Laboratory studies revealed absent endometrial tissues, absent urinary gonadotrophins, and low urinary œstrogens; there was no evidence of intrasellar disease. This patient was treated with human menopausal urinary gonadotrophin (HMGFSH; 'Pergonal'; Cutter Laboratories) and human chorionic gonadotrophin (HCG; 'APL'; Ayerst Co.).

Patient 2, a 34-year-old housewife, complained of amenorrhœa of eight years duration, unassociated with lactation, following an otherwise uncomplicated early miscarriage. The only significant findings on physical examination were small ovaries and uterus. Laboratory examination revealed absent endometrial tissue, absent urinary gonadotrophins, and low urinary œstrogens. This patient was given daily an amount of human pituitary follicle stimulating hormone (HPFSH; kindly provided by Dr. A. Albert of Merck and Co.) equivalent to 20 mg of Armour standard '264-151*X*' FSH; this was combined with HCG ('APL'-Ayerst and Co.).

Patient 3 is a 26-year-old married woman with proved ovulatory cycles by measurements of basal-body temperature and measurements of urinary pregnanediol. However, a two-year history of infertility of unknown cause exists. On examination, the only remarkable findings were urinary levels of 17-ketosteroids which were repeatedly in the upper range of normal (15 mg/24 h) and elevated plasma levels of dehydroepiandrosterone sulphate in excess of 350 μg/100 ml.; the latter compares with normal values of < 200 μg/100 ml. Since these abnormalities are totally suppressible with exogenous corticoids and ovulatory cycles persist, no sustained suppressive therapy has been carried out.

Patient 4 is a 23-year-old single woman with regular ovulatory cycles confirmed by repeated measurements of basal-body temperature and by measurements of an elevated excretion of pregnanediol during luteal phase. No evidence of endocrinopathy was noted.

* Post-doctoral Fellow (*PF*-1-63) of the United Cerebral Palsy Foundation; present address: Department of Pediatrics, University of California, San Francisco Medical Center, San Francisco, California.

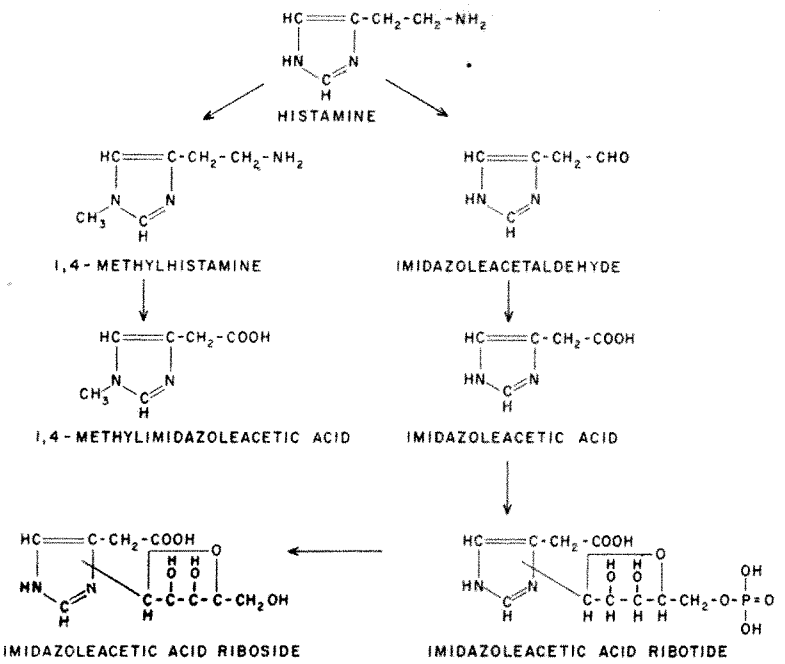

Fig. 1. The major pathways for the metabolism of histamine (refs. 1–4).

Total œstrogens were measured[9] in 24-h urine specimens. Histamine was measured on 24-h urine specimens without knowledge of the source of the urines or of œstrogen-levels. Histamine was measured in duplicate samples of 10 ml. of urine by an adaptation[10] of the fluorometric method[11]. Internal and external standards of 0·25 and 0·50 μg were routinely run, in addition to reagent blanks. Normal women excrete 15–46 μg of histamine/24 h[7].

Methylhistamine, also, was measured on 24-h specimens without any knowledge of the source of the urine or of œstrogen-levels. Methylhistamine was measured in duplicate samples of 10 ml. of urine by a method[7] based on the formation and extraction of dinitrophenylmethylhistamine[12]. Duplicate samples usually agreed within 2–3 per cent and never deviated by more than 10 per cent. The validity of the method has been established by various chromatographic procedures and by experiments in which specific activity of the product was measured[7]. Reagent blanks, together with internal and external standards of 1–4 μg, were routinely run. Normal women excrete 137–444 μg of methylhistamine/24 h[7].

Samples of urine were taken to *p*H 13 or greater with 10 N sodium hydroxide, saturated with sodium chloride, and shaken for 10 min with 1 vol. of a solution containing equal parts, by vol., of 1-butanol and chloroform. After centrifugation at 10,000*g* for 5 min the organic (upper) layer was added to 1·5 vol. heptane and 0·1 vol. of 0·2 N hydrochloric acid. The mixture was shaken for 5 min and then centrifuged at 500*g* for 2 min. The aqueous (lower) layer was dried under reduced pressure in an evaporator. The material was dissolved in 0·5 ml. of water, adjusted to *p*H 9 with 2 M sodium carbonate, and dried under reduced pressure. To the residue was added 0·08 ml. of an aqueous solution containing 0·2 M sodium carbonate–sodium bicarbonate buffer, *p*H 10·6, and 0·004 M sodium diethyldithiocarbamate; to this mixture was then added 0·08 ml. of a solution containing 0·24 ml. of fluoro-2,4-dinitrobenzene in 5 ml. of absolute ethanol. After 20 min at room temperature, the reaction was stopped by the addition of 1·4 ml. of 0·1 N hydrochloric acid. To this solution were added 0·5 ml. of 2 M sodium carbonate and 1 ml. of *sym*-tetrachloroethane; the mixture was shaken for 30 sec. The upper (aqueous) layer was aspirated and discarded, and the lower (organic) layer washed twice with 1 ml. of 0·05 M sodium carbonate. To the organic layer, 1 ml. of a mixture of 0·5 N hydrochloric acid : 1-butanol (97 : 3, v/v) was added, and the mixture was shaken for 30 sec. From the upper (aqueous) layer, 0·85 ml. was removed, transferred to another tube, and evaporated to dryness under reduced pressure. The yellow residue was dissolved in 0·04 ml. methanol and spotted on plates layered with 0·25 mm of silica gel ('Adsorbosil 1', Applied Science Laboratories). The plates were developed for 90 min in a mixture of 1-butanol : acetic acid : water (60 : 15 : 25). At the R_F corresponding to 2, 4 - dinitrophenylmethylhistamine, the silica gel was scraped from the plate and shaken with 0·35 ml. of a mixture of 0·5 N hydrochloric acid : 1-butanol (97 : 3). The solution was centrifuged at 500*g* for 5 min to remove the silica gel, the supernatant solution was placed in a micro-cuvette and the absorption was read in a Beckman *DU* spectrophotometer at a wave-length of 358 mμ.

Excretion of methylhistamine, histamine, and œstrogen after the administration of gonadotrophic hormones. The administration of human menopausal gonadotrophin or human chorionic gonadotrophin to Patient 1 (Fig. 2) caused no significant increase in urinary œstrogens: over the course of therapy they rose from 14·8 only to 19·9 μg/24 h. During this period, the amounts of histamine fell from 61 to 48 μg/24 h, values which are still above the normal range of 15–46 μg/24 h; methylhistamine decreased from 270 to 200 μg/24 h; and the ratio of methylhistamine to histamine, which was abnormally low (4·4) at the start of therapy, never exceeded 5·5, still a low value.

After 4 months, Patient 1 was again treated with human chorionic gonadotrophin, this time at a higher dose (Fig. 3). Again there was only a slight increase in œstrogen excretion, which rose from 19 to 31·5 and then fell to 14·4 μg/24 h. During this period, the amount of urinary methylhistamine also changed slightly, falling from 210

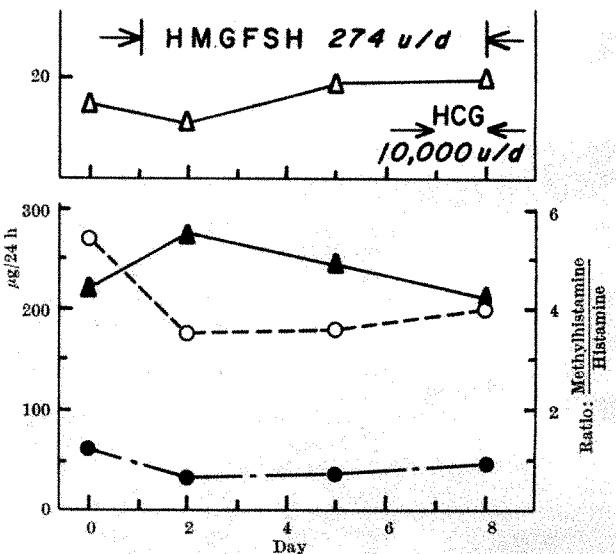

Fig. 2. The urinary excretion of œstrogen and methylhistamine, and the ratio of methylhistamine to histamine, after the administration of human menopausal urinary gonadotrophin (HMGFSH) and human chorionic gonadotrophin (HCG) to Patient 1. There was no consistent change induced by the trophic hormones

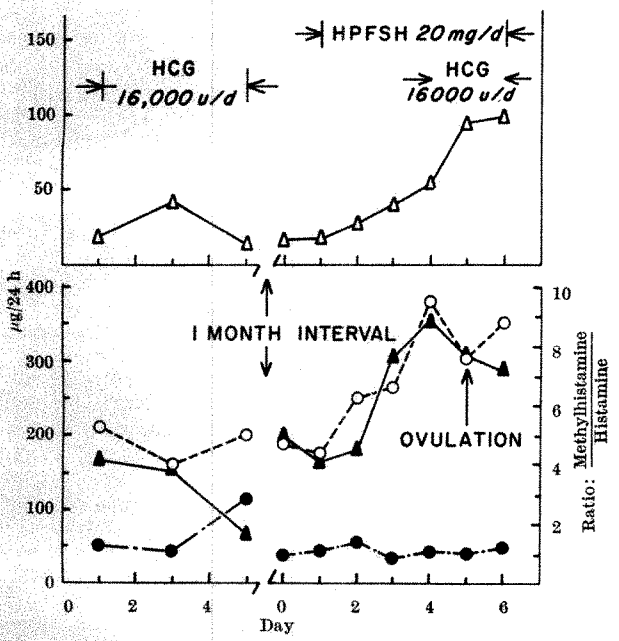

Fig. 3. The increase in the ratio of methylhistamine to histamine in the urine of Patient 1, coincident with the response to human pituitary follicle stimulating hormone (HPFSH) and human chorionic gonadotrophin (HCG), as manifest by the increase in œstrogen excretion. The change in ratio is attributable to a rise in methylhistamine. Symbols are the same as in Fig. 2

to 160 μg/24 h, and then rising to 200 μg/24 h. But there was a significant increase in histamine, which rose from 50 to 115 μg/24 h, causing a significant reduction in the ratio of methylhistamine to histamine, from 4·2 to 1·7, a fall which is not correlated with the excretion of œstrogen and remains inexplicable.

After an interval of 1 month, the same patient was given a course of therapy with human pituitary follicle stimulating hormone and, later, human chorionic gonadotrophin was added (Fig. 3). Œstrogen excretion rose from hypogonadal levels of 15·6 to 102·9 μg/24 h. During this increase, the excretion of histamine was slightly but inconsistently altered, remaining higher than normal. But the excretion of methylhistamine increased from 190 to 380 μg/24 h, a rise that closely paralleled the increase in the ratio of methylhistamine to histamine, which attained a peak value of 8·9. The highest values of both these measurements were obtained the day before ovulation when the œstrogen excretion was 54·7 μg/24 h. At ovulation the ratio of methylhistamine to histamine was 7·7, within the normal range.

Patient 2 responded to treatment with human pituitary follicle stimulating hormone and human chorionic gonadotrophin with a marked increase in the excretion of œstrogen, from the hypogonadal value of 13·2 μg/24 h (Fig. 4). More striking than the elevation in urinary œstrogen was the rise in the ratio of methylhistamine to histamine, which reached a peak of 8·9 at ovulation, when the œstrogen excretion was 167·3 μg/24 h. Three days after ovulation, the œstrogen excretion was 232 μg/24 h; at this time the ratio of methylhistamine to histamine had fallen to 7·0. When this ratio had fallen further, to the abnormally low value of 4·3, the œstrogen excretion had fallen to hypogonadal values of 19·9 μg/24 h.

The change in ratio in this patient (Fig. 4) was almost entirely attributable to a change in urinary histamine; this fell from the initial and abnormally high value of 140 μg/24 h to a low value of 18 μg/24 h which coincided with ovulation. The change in urinary methylhistamine was neither consistent nor marked. This pattern of response in Patient 2 may be compared with that obtained in Patient 1 (Fig. 3), whose changing ratios of methylhistamine to histamine reflected changes in the excretion of methylhistamine. Patient 2 (Fig. 4) also excreted much greater quantities of œstrogen than did Patient 1 (Fig. 3).

Excretion of methylhistamine, histamine, and œstrogen by two normally menstruating women (Table 1). Patient 3 showed normal urinary œstrogen levels, but the ratio of methylhistamine to histamine, in both the pre-ovulatory and post-ovulatory samples, were abnormally low, 3·5 and 2·3 respectively. Both these low values are attributable to abnormally high urinary histamine; the excretion of methylhistamine was within the normal range. Patient 4 had normal values of œstrogen, histamine, and methylhistamine, and normal ratios of methylhistamine to histamine. Patient 4 has no known endocrine problem. Patient 3 has a fertility problem and has abnormally high plasma levels of androgens.

Table 1. Estimates of Urinary Excretion of Methylhistamine, Histamine, and Œstrogen in Two Normally Menstruating Women

	Methylhistamine (μg/24 h)	Histamine (μg/24 h)	Ratio, $\frac{\text{Methylhistamine}}{\text{Histamine}}$	Œstrogen (μg/24 h)
Patient 3				
Pre-ovulatory (day 10)	330	94	3·5	28·3
Post-ovulatory (day 23)	324	140	2·3	45·3
Patient 4				
Pre-ovulatory (day 10)	270	30	9·0	29·9
Post-ovulatory (day 23)	310	40	7·7	54·6

Before therapy with gonadotrophic hormones, the two hypogonadal women had low ratios of methylhistamine to histamine, attributable mostly to high urinary histamine. One of the patients had a ratio of 1·1 (Fig. 4); the other, in three separate measurements, had ratios of 4·4, 4·2 and 4·9 (Figs. 2 and 3). These compare with ratios of 7–9·1 in normal women and of 6–15 in normal men[7]. After receiving gonadotrophic hormones, these ratios increased, coincident with the production of œstrogen by the ovarian follicle, and reached a peak at ovulation (Figs. 3 and 4). It is interesting that the ratio became normal when the amount of œstrogen became normal, and these ratios did not further increase even though the amount of œstrogens increased further (Figs. 3 and 4). With a fall in œstrogen excretion, the ratio of methylhistamine to histamine in urine also fell (Fig. 4).

That factors other than œstrogen are important in contributing to the ratio is indicated in Table 1. Patient 3, who was having ovulatory menses but having an infertility problem, showed normal œstrogen excretion but had a low ratio of methylhistamine to histamine, which was attributable to high urinary histamine; it may be significant that this patient shows abnormally high plasma-levels of androgens, which can be synthesized by the human ovary[13]. Patient 4 had normal œstrogen excretion, normal amine-levels and normal ratios. After ovulation, both patients 3 and 4 showed increased amounts of œstrogen, with no rise in the ratio of methylhistamine to histamine (Table 1). Further evidence that the œstrogens themselves are not wholly responsible for the relative increase in the ratio was obtained in a patient whose ratios fell after she received œstrogen[7]. It is suggested that the high urinary ratio of methylhistamine to histamine is in part due to a direct action of œstrogen and in part due to other factors and events contributing to the œstrogen response, perhaps to other activities of the ovarian follicle such as the production of androgens.

In the absence of an œstrogenic response, the ratio was not altered (Fig. 2), but concomitant with an œstrogenic response the ratio increased (Figs. 3 and 4). In the patient with a relatively weak œstrogenic response, the increase in the ratio was attributable to a rise in methylhistamine (Fig. 3); in the patient with a strong œstrogenic response the increase in ratio was due to a fall in histamine (Fig. 4). This difference suggests that factors contributing to and accompanying the œstrogenic response may influence

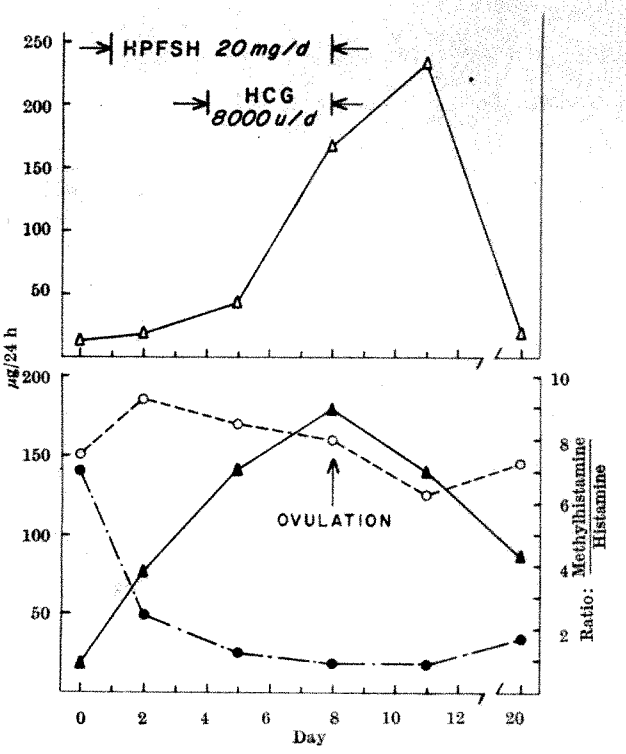

Fig. 4. The increase in the ratio of methylhistamine to histamine in Patient 2, coincident with the response to human pituitary follicle stimulating hormone (HPFSH) and human chorionic gonadotrophin (HCG) as manifest by the increase in œstrogen excretion. The change in ratio is attributable to a fall in histamine. The symbols and abbreviations are the same as in Fig. 2

the disposition of histamine by acting at more than one site. One such site, it may be suggested, could be an inhibition of monoamine oxidase activity, which would result in a rising methylhistamine, but such inhibition is most unlikely, for one would expect that with a further increase in the œstrogenic response (Fig. 4) the methylhistamine would increase further, but it did not.

The sites are not immediately discernible, for although much is known of the effects of hormones on histamine metabolism in the rat[14,15], caution must be exercised in extrapolating these results to man: a pertinent and conspicuous example of the species differences is that female rats excrete much more histamine that do males[14,15], but in man there is no difference between the sexes[7,10]. However, there are investigations of histamine metabolism in man which may help to explain our findings.

Œstrogen disrupts mast cells in both the endometrium and myometrium of the human being[16], guinea-pig[17], and rat[18] uteri. As a consequence of the destruction of the mast cells (and perhaps because of an increased synthesis of histamine by other cells[19,20]) histamine is released[18,21]. An œstrogen-induced release of histamine is further indicated by the increased excretion of histamine seen in pregnancy[7,22] and after the administration of an œstrogen preparation[7]. It has, in fact, been suggested that œstrogen (and luteinizing hormone) owe at least some of their effects on the uterus to a release of histamine[18,21,23], which has been detected in the discharge from the human uterus[24]. As judged from the guinea-pig uterus, the mast cells of which respond to œstrogen as do the mast cells in human uterus[17], the uterine mast cells more readily fragment and release their histamine than do mast cells in other organs[25,26]. It may be presumed that there is a continual formation of mast cells and, with the œstrogenic response, a continual dissolution.

In order to explain the increase in urinary methylhistamine concomitant with a relatively slight change in histamine (Fig. 3), it is suggested that the histamine released by the relatively low œstrogenic response is catabolized in the normal manner to methylhistamine. When the œstrogenic response is increased still further (Fig. 4), a greater portion of the released histamine is catabolized by diamine oxidase, which results in a diminished histamine but unchanged methylhistamine.

There is no definitive evidence that the œstrogenic response either inhibits the methylation of histamine or activates its oxidation. The only relevant investigations on human beings were carried out with exogenous histamine, the disposition of which does not necessarily reflect the disposition of endogenous histamine[27–31]. However, in the experiments with exogenous histamine, it was shown that in human pregnancy, where the œstrogenic response is high, the capacity of the uterus to methylate histamine is reduced, an unusually high proportion of histamine being oxidized[32,33]. Moreover, the plasma of pregnant women is extremely high in diamine oxidase activity[6]. An increase in uterine diamine oxidase activity, induced by a strong œstrogenic response, together with high plasma diamine oxidase activity could explain the falling levels of histamine in urine (Fig. 4); this postulate can be tested when a method becomes available to measure imidazoleacetic acid. Although these observations on pregnant women may help to explain our findings, it should be emphasized that histamine metabolism in pregnancy is influenced by factors other than an œstrogenic response, as manifest by the high levels of histamine found in the urine of pregnant women[7,22], a rise that may be reflective of fœtal growth[20,34].

The tests of the postulates presented here must await the development of methods to measure other endogenously formed catabolites of histamine. Whether or not the postulates are correct does not detract from the salient fact: stimulation of the ovarian follicle in women is correlated with the metabolism of endogenous histamine.

NAD$^+$-GLYCOHYDROLASE OF THYROID HOMOGENATES

By DR. MORELLY L. MAAYAN

Pratt Clinic–New England Center Hospital and Department of Medicine, Tufts University School of Medicine, Boston, Mass.

RECENT investigations have shown the importance of the pyridine nucleotides in the energetic[1,2] and iodine[3–8] metabolism of the thyroid gland.

The work recorded here demonstrates the enzymatic inactivation of di- and tri-phosphopyridine nucleotides in thyroid homogenates by NAD$^+$-glycohydrolase. The existence, mode of action, *trans*glycosidase activity, analogue-formation capacity and specific inhibition of this enzyme have been described for different tissues in earlier publications[9–25].

The experiments presented here fall into three groups:

Group A. Thyroid homogenates were prepared from glands of human beings and pigs, as described by Zatman *et al.* for the bovine spleen[18], and the protein content was measured[26]; 0·2-ml. samples were added to 1 ml. of 0·1 M phosphate buffer at *p*H 7·4, containing NAD or NADP at 20 different concentrations (0·1–2 mmoles/l.) and incubations were carried on for 10 min at 37° C in a Dubnoff metabolic incubator. The pyridine nucleotides were determined by their absorption at 325 mμ in a Beckman *DB* spectrophotometer, after addition of M KCN[27]. The results indicated a gradual disappearance of NAD and NADP, increasing with the pyridine nucleotide concentration (Fig. 1).

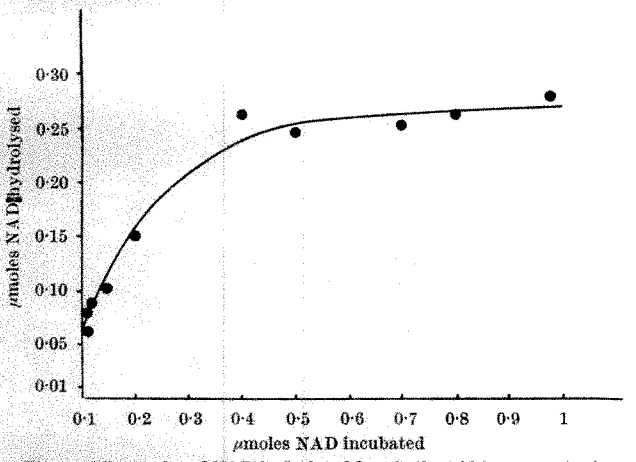

Fig. 1. Micromoles of NAD hydrolysed by pig thyroid homogenates in presence of various concentrations of NAD

When the results were plotted as $1/s$ over $1/v$ following the Lineweaver and Burk method[28], the *Km* from several determinations was between $1·5–3·5 \times 10^{-4}$ M for NAD and $1·9 \times 10^{-4}$ M for NADP. Addition of nicotinamide at a final concentration of $7·5 \times 10^{-2}$ M inhibited 90 per cent of the pyridine nucleotide disappearance. Incubations with 16 different concentrations of nicotinamide (1×10^{-5} M – $7·5 \times 10^{-2}$ M) indicated 50 per cent inhibition with $1·5 \times 10^{-3}$ M for NAD and NADP in agreement with previous findings for the enzyme of other tissues[14,15,29].

Table 1. Percentage of NAD and NADP disappearing during incubation for 10 min with 0·2 ml. pig thyroid homogenate in medium containing $1·5 \times 10^{-2}$ M nicotinamide or nicotinamide-free. The results indicate the non-competitive character of the nicotinamide inhibition

	NAD				NADP		
Incub.	End of incubation 0	End of incubation Nicotinamide	% of disap.	Incub.	End of incubation 0	End of incubation Nicotinamide	% of disap.
1 μM	0·063 μM	0·033 μM	52·0	1 μM	0·061 μM	0·029 μM	47·5
2 μM	0·154 μM	0·07 μM	48·7	2 μM	0·160 μM	0·083 μM	51·8
5 μM	0·240 μM	0·119 μM	49·5	5 μM	0·231 μM	0·123 μM	48·9

Incubation of 20 different concentrations of NAD and NADP in the presence of four different concentrations of nicotinamide indicated the non-competitive nature of this inhibition (Table 1). When data resulting from incubation of NAD and NADP in media free of nicotinamide (*A*) and containing nicotinamide (*B*) were plotted as $1/s$ over $1/v$, the intercept of *A* with $1/v$ was at a lower point than of *B* with $1/v$, confirming the non-competitive nature of the nicotinamide inhibition (Fig. 2).

Confirmatory evidence of NAD$^+$-glycohydrolase presence was brought by incubation at 37° C of 1 ml. of human or pig thyroid homogenate in 3·5 ml. of 0·1 M phosphate buffer at *p*H 7·4 in presence of 6×10^{-4} M NAD or NADP and 2×10^{-2} M isoniazid (INH) leading to the gradual formation of INH analogue, demonstrated by the appearance of yellow colour and of the absorption spectrum with a peak of 385 mμ in alkaline *p*H (refs. 17 and 18). 6-*N*-Propylthiouracil, methyl-mercaptoimidazole, perchlorate, thiocyanate, iodine, monoiodotyrosine, L-diiodotyrosine, triiodothyronine and thyroxine in concentrations between 1×10^{-5} M and 1×10^{-2} M did not inhibit NAD or NADP hydrolysis by thyroid homogenates. No analogue formations with substances other than INH were followed in the work recorded here.

Group B. Results in the literature[30] report, with one exception[12], the inability of the NAD$^+$-glycohydrolase to hydrolyse the reduced forms of NAD and NADP.

Incubating 3 ml. of 0·1 M phosphate buffer *p*H 7·4 containing 1 μmole of NADH or NADPH with 0·2 ml. human or pig thyroid homogenate for 10 min at 37° C, spectrophotometric readings at 340 mμ and fluorometric determinations[31] indicated disappearance of the reduced pyridine nucleotides. As this could have been the result of oxidative processes in the thyroid homogenates[5,27], retrieval of the oxidized forms was attempted either by addition of corresponding reducing systems or by fluorometric determinations[31]. Both methods demonstrated a marked disappearance of NADH and NADPH. It was therefore supposed that the reduced forms of NAD and NADP are first oxidized and afterwards hydrolysed by thyroid homogenates.

The following experiment was designed to substantiate this supposition:

One ml. of human or pig thyroid homogenate was incubated for 24 h at 37° C in 0·1 M phosphate buffer *p*H 7·4,

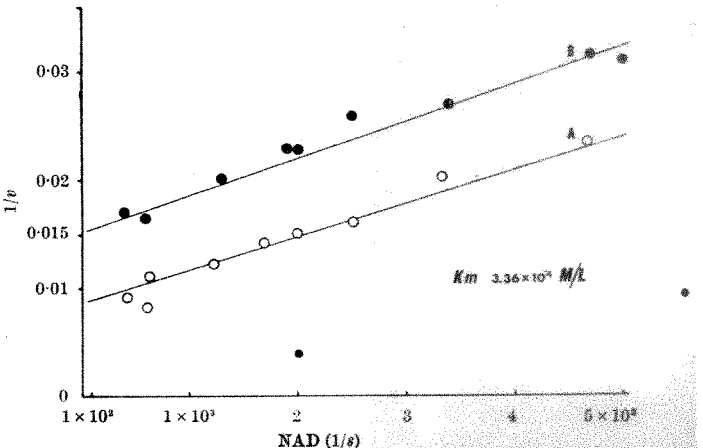

Fig. 2. *Km* of NAD for pig thyroid homogenates. *A*, incubated in 0·1 M phosphate buffer; *B*, 5×10^{-2} M nicotinamide was added to the incubation medium

containing 6×10^{-3} M NADH or NADPH and 2×10^{-2} M INH. After destroying the reduced pyridine nucleotides by addition of 0·1 N HCl, the medium was brought to alkaline *p*H (9·5) by addition of 1 N NaOH. Appearance of a yellow colour and an absorption spectrum with a peak of 385 mμ demonstrated the presence of the INH analogue in the medium.

I think this experiment demonstrates that, under the conditions prevailing in a thyroid homogenate, the concentration or availability of reduced pyridine nucleotides might be influenced by the NAD^+-glycohydrolase activity, subsequent to their oxidation.

Group C. Enzymatic deiodination of the iodotyrosines requires the presence of NADPH[3,4]; its rate is dependent on the quantity or availability of this co-factor[8,32]. Liver homogenates incubated in medium containing nicotinamide exhibit an increased deiodinating capacity[3]. NADase of *Neurospora crassa* added to a thyroid homogenate induces a fall in its deiodinating capacity[3].

These findings justify the presumption that the NAD^+-glycohydrolase of the thyroid tissue may influence the thyroidal enzymatic deiodination of iodotyrosines. The NAD^+-glycohydrolase inhibition by nicotinamide was used to demonstrate this point.

The deiodinating activity of thyroid glands of normal rats was examined, as previously described[8], and found to be markedly enhanced when $7{\cdot}5 \times 10^{-2}$ M nicotinamide was present in the medium (Table 2).

Table 2. Micrograms of L-DIT deiodinated per mg in 2 h by rat thyroids homogenized in 10 vol. of buffer in presence of various concentrations of nicotinamide

Nicotinamide	
0	0·0019 ± 0·0001
$7{\cdot}5 \times 10^{-3}$ M	0·0126 ± 0·0004
$7{\cdot}5 \times 10^{-2}$ M	0·0212 ± 0·0006

The deiodinating capacity of thyroid homogenates increased linearly with the nicotinamide concentration (Fig. 3).

When thyroid homogenates were incubated in NADPH-enriched media, and 5×10^{-2} M nicotinamide added, the resulting *Km* for the co-factor was 5×10^{-5} moles/l. instead of $1–2 \times 10^{-4}$ moles/l. observed in a nicotinamide-free medium[32], that is, a 10 times reduction of the optimal concentration of NADPH for 50 per cent of the maximum velocity of the deiodinating enzyme (Fig. 4).

The enhancing effect on deiodination of nicotinamide addition disappeared when:

(*a*) The rat thyroid glands were homogenized in 100 volumes of the incubation medium, presumably because the NAD^+-glycohydrolase is too weak to hydrolyse the co-factor substantially so that its inhibition is ineffective.

(*b*) The rat thyroid glands were homogenized in 10 volumes of buffer containing a NADPH oxidizing system (oxidized glutathione and glutathione reductase) showing

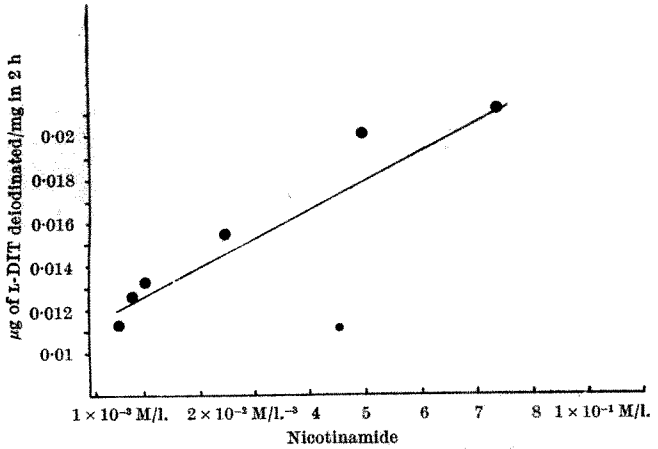

Fig. 3. Micrograms of L-DIT deiodinated per mg of rat thyroid tissue homogenized in ten volumes of buffer containing various concentrations of nicotinamide

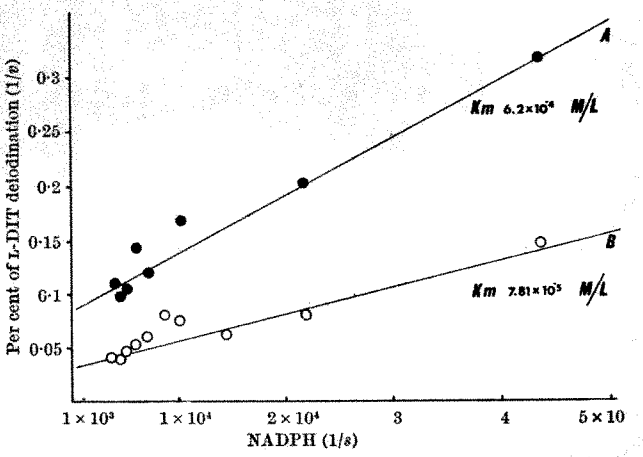

Fig. 4. *Km* of TPNH in L-DIT deiodination by rat thyroids homogenized in ten volumes of medium nicotinamide-free (*A*) and containing 5×10^{-2} M nicotinamide (*B*); 10 min incubation

that nicotinamide does not directly enhance deiodination in the absence of reduced NADP.

It may, therefore, be concluded that:

(*a*) NAD^+-glycohydrolase activity, demonstrated in thyroid homogenates, might influence the tissue concentration of pyridine nucleotides and, thus, those steps of the thyroidal metabolism which required the presence of co-factors[1–9].

(*b*) NAD^+-glycohydrolase transglycosidase capacity to form NAD or NADP analogues might prove useful in future experiments designed to explain the mechanism of action of antithyroid drugs.

I thank Dr. M. Raben for his assistance and advice.

MECHANISMS OF REGULATION OF HEPATIC GLYCOGEN SYNTHESIS

By Prof. DONALD F. STEINER*

Department of Biochemistry, University of Chicago, Illinois

MANY factors influence glycogen storage in the liver by ultimately affecting either the rate of synthesis or of degradation of the α 1,4 linkages of the glucose polymer. Both the enzymes concerned with this process, UDPG-glycogen glucosyl-transferase (*EC* 2.4.1.11) and phosphorylase (*b*-form, *EC* 2.4.1.1), are now known to have binding sites for certain intra-cellular metabolites which act as allosteric regulators of enzyme activity[1]. Glucose-6-P is the only such metabolite known to regulate the synthesis of glycogen by combining specifically with the enzyme protein. This property of glucosyltransferase appears to be a universal feature of the enzyme from widely divergent sources. Several structural features essential for stimulation by aldohexose phosphates have been defined[2].

Measurements of hepatic glucose-6-P levels in various metabolic states such as repletion, fasting, and diabetes[3] indicate that the steady-state concentration of this metabolite fluctuates widely over a range which coincides closely with the *Km* concentration for glucose-6-P of hepatic glucosyltransferase, and which could, therefore, significantly modify enzyme activity *in vivo*. Several lines of indirect evidence suggest that this mechanism plays an important part in the increased glycogen synthesis which occurs when normal animals are given glucose after a short fast, and also when fasted normal or adrenalectomized animals are given cortisol. In both instances the concentration of hepatic glucose-6-P rises several-fold from significantly depressed levels[3,4]. That the rise in glucose-6-P in normal fasted animals is due primarily to increased glucose phosphorylation is shown by the data of Hers[5], who found that glucose-1-^{14}C is incorporated into liver glycogen without significant redistribution of label when administered to rats fasted 24 h or less. The increase in glucose phosphorylation appears to be due to the presence of a specific glucokinase in liver which has a high *Km* for glucose[6], and which can therefore respond to variations in plasma glucose concentration. The results of an experiment are presented in Table 1, in which fasted normal rats were given glucose injections. At later intervals the livers were removed and the activities of both glucokinase and UDPG-glycogen glucosyltransferase measured. Glucosyltransferase activity increased only slightly after 60 and 100 min, and no change in glucokinase activity occurred. Similar observations with respect to glucosyltransferase activity have been made in animals treated with cortisol[4,7]. However, with cortisol, increased glucose-6-P is derived primarily from the stimulation of gluconeogenesis rather than of glucose phosphorylation although blood glucose concentration is increased by cortisol. In both these instances it is evident that the synthesis of increased amounts of glycogen is initiated by changes in concentration of critical extra-cellular and intra-cellular metabolites rather than by changes in concentration of enzymes.

By contrast, when diabetic or starved animals are given insulin or food respectively, initiation of glycogen synthesis is attendant with the synthesis of glucosyltransferase in increased amounts without an increase in either glucose-6-P concentration or glucose phosphorylation. Fed alloxan diabetic animals have low liver glycogen and glucose-6-P levels despite increased gluconeogenesis and marked alimentary hyperglycæmia[3]. Hepatic glucokinase is markedly reduced and glucose-6-P phosphatase increased in the diabetic organism. When insulin is given to these animals, glycogen repletion begins within about 40 min and enormous amounts of glycogen accumulate

Table 1. Effect of Glucose on Hepatic UDPG-Glycogen Glucosyltransferase Activity, Glucokinase Activity, Glycogen Concentration and Blood Glucose Concentration in Fasted Normal Rats

Group	No. of animals	Glucosyltransferase activity (μmoles/g protein/h) − G-6-P	Glucosyltransferase activity (μmoles/g protein/h) + G-6-P	Glucokinase activity (μmoles/g protein/h)	Glycogen conc. (mg/g)	Blood glucose (mg/100 ml.)
Control (saline)	7	74 ± 3·8	375 ± 17	235 ± 12	3·4 ± 0·4	79 ± 1·3
Glucose, 60 min	4	115 ± 2·7	390 ± 10	—	5·5 ± 0·7	99 ± 3·1
Glucose, 100 min	3	127 ± 14	455 ± 19	246 ± 7·0	9·6 ± 0·7	124 ± 5·2

Female Sprague-Dawley rats, fasted 18–20 h, were given intraperitoneal injections of 5 c.c. of 5% dextrose solution or 0·9% saline solution. The animals were killed at the times indicated and the livers perfused with cold 0·3 M sucrose, 0·005 M EDTA, *p*H 7·4, via the portal vein. The preparation of homogenates, assay and other analytical procedures have been described (refs. 7 and 8).

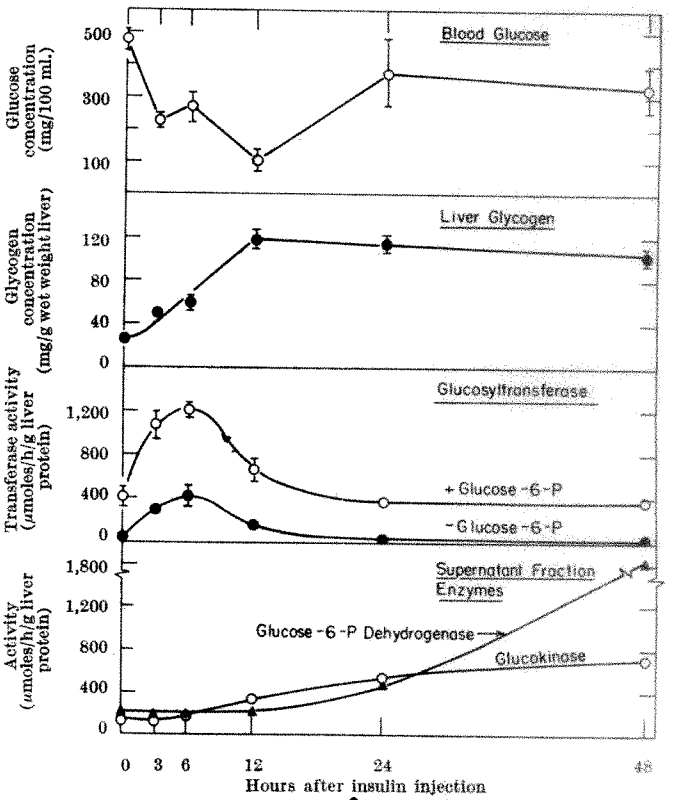

Fig. 1. Effect of insulin administration for 48 h on blood glucose and liver glycogen concentration, UDPG-glycogen glucosyltransferase activity, and the activities of several enzymes of the supernatant fraction in severely diabetic rats. The animals received intraperitoneal injections of 5·0 units of glucagon-free insulin and subcutaneous injections of 6 units of protamine zinc insulin (Lilly) at zero time. The rats to be killed at 48 h were given another injection of 4 units of protamine zinc insulin subcutaneously at 24 h. The animals were killed at the times indicated, and assays were carried out as described (refs. 7 and 8). Each point represents the average of at least three determinations, and brackets indicate *S.E.M.*

* Holder of a Research Career Development Award of the U.S. Public Health Service.

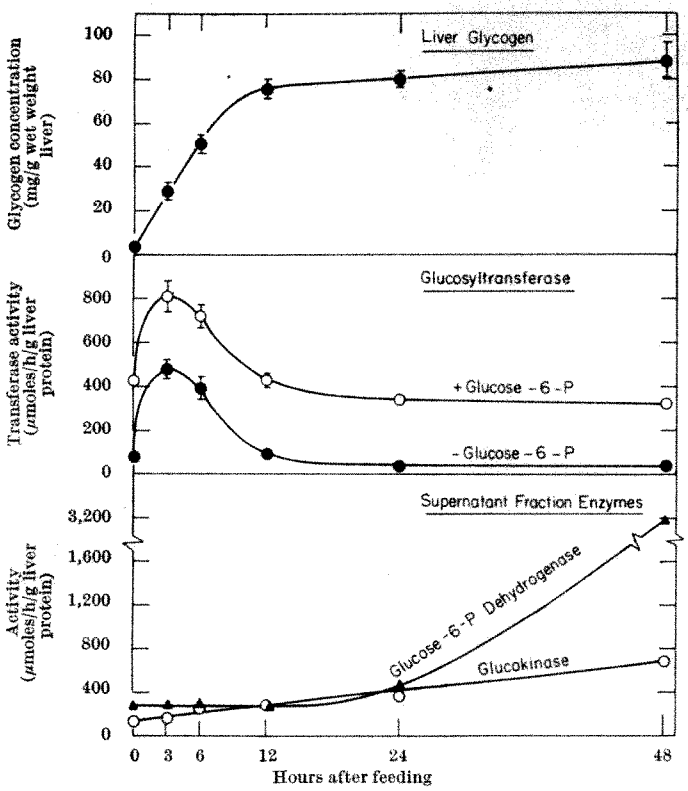

Fig. 2. Effect of re-feeding with a standard laboratory diet (Rockland Rat Diet) for 48 h on blood glucose and liver glycogen concentration, UDPG-glycogen glucosyltransferase activity, and the activities of several enzymes of the supernatant fraction in normal rats fasted 72 h. The animals were killed at the times indicated, and assays carried out as described (refs. 7 and 8). Each point represents the average of four determinations, and brackets indicate *S.E.M.*

during the first 12-h interval of administration of insulin[8]. These deposits persist in the liver for several days while other metabolic transitions ensue, but are eventually dispersed when normal blood glucose-levels are achieved. Glucose-6-P measurements during the initial period of rapid glycogen deposition show only a transient decrease in concentration[3] in contradistinction to the marked rise seen in the two circumstances discussed before.

This is not surprising in view of the recent finding in several laboratories[9] that insulin-dependent synthesis of liver glucokinase does not begin in diabetic animals until about 6 h after insulin is first administered. Restoration of this enzyme to normal levels probably accounts for the increased glucose phosphorylation observed 6–24 h after insulin administration by Renold *et al.*[10] during examination of liver slices from diabetic rats. The early stimulation of glycogen synthesis under these conditions cannot therefore be ascribed to increased glucose phosphorylation, but rather, appears to result from operation of a second control mechanism which acts to increase the rate of synthesis of the enzyme, UDPG-glycogen glucosyltransferase. The results in Fig. 1 illustrate the relationship of changes in liver glycogen concentration to changes in activity of glucosyltransferase, glucokinase and glucose-6-P dehydrogenase following administration of insulin to alloxan diabetic rats. The glucosyltransferase activity rises sharply beginning about 40 min after the first injection of insulin and reaches peak levels by about 6 h at which time glucokinase activity is just beginning to increase. Glucose-6-P dehydrogenase also increases dramatically after insulin but does not begin to rise until 12 or more hours after the first injection of insulin. The glucosyltransferase increase is inhibited completely by both puromycin and actinomycin *D*, and partially by ethionine, *in vivo*[8].

These findings are regarded as strongly suggestive evidence for the existence of a control mechanism for enzyme synthesis which operates at the level of transcription of messenger RNA from the structural gene for the enzyme protein. In contrast to the induction of many other mammalian enzymes, including the others shown in Fig. 1, the induction of glucosyltransferase has a short lag period of only 40 min, and it later decays with a relatively short half-life of about 4 h. Since the inductions of glucosyltransferase, glucokinase, and glucose-6-P dehydrogenase follow sequentially, and with highly individual patterns, it seems quite unlikely that the genes for these three enzymes are grouped within a single operon, as has been suggested for several other groups of closely related hepatic enzymes[11].

The metabolic transitions brought about by insulin in diabetic rats are almost identical to those which follow the restoration of a balanced diet to normal animals fasted for prolonged periods (3–4 days). Fig. 2 presents the results of an experiment in which liver glycogen concentration and the activities of UDPG-glycogen glucosyltransferase, glucokinase, and glucose-6-P dehydrogenase were followed for 48 h after re-feeding rats fasted for three days. It is noteworthy that the glucosyltransferase increase as well as the peak glycogen concentration are both smaller in magnitude than in the insulin-treated severely diabetic rats (Fig. 1) and, also, the peak enzyme-level is reached at an earlier time. Salas *et al.*[9] have observed similarly that liver glucokinase responds more rapidly to re-feeding in normal rats than in insulin-treated diabetic rats, rising as early as 3–4 h after re-feeding. Why this is seen in the induction of both these enzymes is not clear, but may be related to the greater severity of the metabolic derangements in chronic diabetes. Measurements of hepatic glucose-6-P concentration in rats fasted three days and then re-fed a balanced diet or given glucose solution[3,12] indicate that, despite a considerable elevation of the glucose concentration in the blood, no significant rise in concentration of glucose-6-P occurs in the liver, just as with diabetic animals after insulin injections. It can be concluded that, in the foregoing two metabolic states, increased glycogen synthesis is initiated by an increase in the amount of glucosyltransferase enzyme rather than by a rise in the steady-state level of glucose-6-P.

As shown by these experiments and others cited, insulin appears to be of critical importance for an integrated sequence of metabolic readjustments which occurs in the liver during the transition from a starved or diabetic state to the normal fed state. The role of insulin in such hepatic adaptations has often been ignored, while attention has been directed solely to dietary factors without due consideration of the endocrine consequences during re-feeding. To evaluate further the role of insulin, normal rats were fasted for three days, and just before re-feeding, some were given intraperitoneal injections of guinea-pig anti-insulin serum or non-immune serum. Those receiving the insulin anti-serum ingested food normally for about 1 h, but, as shown in Table 2, glycogen deposition and glucosyltransferase induction were abolished almost completely despite the development of significantly higher levels of blood glucose concentration in the acutely diabetic group. These results clearly demonstrate that insulin is essential for this phase of hepatic adaptation to re-feeding. However, in another experiment the administration of a small dose of insulin alone to animals fasted for three days resulted only in severe hypoglycæmia without any increase in glucosyltransferase activity. While this result suggests that some element(s) of the diet may also be indispensable for the induction of this enzyme, compensatory endocrine responses to hypoglycæmia which might inhibit the

Table 2. EFFECT OF ANTI-INSULIN SERUM ON THE RESPONSE TO RE-FEEDING OF HEPATIC UDPG-GLYCOGEN GLUCOSYLTRANSFERASE ACTIVITY, GLYCOGEN CONCENTRATION, AND BLOOD GLUCOSE CONCENTRATION IN RATS FASTED FOR 72 H

Group	No. of animals	Glucosyltransferase activity (μmoles glucose/g protein/h) −G-6-P	+G-6-P	Glycogen conc. (mg/g)	Blood glucose (mg/100 ml.)
Control	3	71 ± 8·8	480 ± 13	2·2 ± 0·6	76 ± 2·2
Re-fed	3	480 ± 107	700 ± 107	28 ± 1·4	113 ± 12
Re-fed + AIGPS	3	118 ± 14	450 ± 21	6·9 ± 1·0	275 ± 3·5
Re-fed + NGPS	3	430 ± 117	680 ± 56	28 ± 2·2	109 ± 7·8

Female Sprague–Dawley rats, fasted for 72 h, were divided into four equal groups. Two groups were given intraperitoneal injections of either 1·5 ml. of normal guinea-pig serum (NGPS) or 1·5 ml. of anti-insulin guinea-pig serum (AIGPS) 20 min before re-feeding, and an additional 1·0 ml. of the same serum 90 min after re-feeding. Control animals were not given food or injections. The animals were killed 3·5 h after re-feeding and the livers perfused with cold 0·3 M sucrose, 0·005 M EDTA, *p*H 7·4, via the portal vein before removal. The preparation of homogenates, assay and other analytical procedures have been described (refs. 7 and 8).

response cannot be excluded. Further investigation is required to clarify these points.

It has been reported recently that synthesis of glycogen in muscle is regulated by a mechanism which can be influenced by insulin and epinephrine, and also by muscle contraction[13]. The central feature of this mechanism is the circumvention of the normal allosteric mechanism for regulation of muscle glucosyltransferase, that is, glucose-6-P dependency, by the conversion of this enzyme to a glucose-6-P independent (I) form by means of a reversible dephosphorylation of the enzyme protein reminiscent of the transformations of muscle phosphorylase[14]. It is not clear at present whether this kind of mechanism, in addition to those discussed earlier in this report, participates in the regulation of glycogen synthesis in the liver, for, in contrast to the more stable muscle glucosyltransferase, the hepatic enzyme readily loses a large proportion of its glucose-6-P dependency on mild heating at 37° in the absence of glucose-6-P, and recovers it on further incubation in the presence of glucose-6-P and certain salts[15]. It is possible that this lability of the allosteric site of hepatic glucosyltransferase may explain the greater glucose-6-P independence of newly synthesized glucosyltransferase (note glucosyltransferase activity in absence of glucose-6-P in Figs. 1 and 2, and in Table 2).

If space allowed, many examples could be cited where selective control of the rate of synthesis of enzymes has been demonstrated by manipulation of the endocrine or nutritional state of animals. The inhibition of such enzyme adaptations by actinomycin *D* is regarded as presumptive evidence that the step in enzyme formation which is subject to control is that of transcription of information from DNA to messenger RNA. While control of transcription of a rapidly turned-over messenger RNA would seem to provide the necessary precision and flexibility of control, and is consistent with hypotheses of bacterial enzyme regulation[16], many problems, which are not yet resolved, have arisen in the application of this simple concept to enzyme synthesis in more complex organisms. For example, there is still considerable uncertainty regarding the stability of the total messenger RNA fraction in tissues such as mammalian liver[17], and, moreover, there are now indications that messenger RNA function may also be subject to regulation[18]. In the case of hormone-dependent acceleration of enzyme synthesis in mammalian tissues there is also considerable doubt that a hormone acts as an inducer or derepressor as defined in the more simple bacterial model, for although the hormone is essential to the process, it appears to be only one component among several which summate to modulate the rate of production of the enzyme protein. This is exemplified by the glucosyltransferase transitions which have been discussed here. The level of this enzyme is not significantly reduced by the insulin deficiency of severe diabetes, and it seems to require the presence of some unknown metabolite(s) in order to be induced by insulin or, conversely, to require insulin for its induction by some metabolite(s). Moreover, in contrast to the adult animal, accelerated synthesis of hepatic glucosyltransferase during the latter stages of gestation of the rat fœtus is dependent on the presence of cortisol rather than insulin[19].

This work was supported by U.S. Public Health Service grant *AM*–04931–04. I thank Miss Judith King for her assistance, and Mr. Lee Younger for preparation of insulin antisera.

PROGNOSIS FOR INTERRUPTION OF MALARIA TRANSMISSION THROUGH ASSESSMENT OF THE MOSQUITO'S VECTORIAL CAPACITY

By C. GARRETT-JONES

Division of Malaria Eradication, World Health Organization, Geneva

WHEREVER malaria eradication relies on vector control, efforts should be made to assess the degree of control achieved and its effectiveness in producing a downward trend in malaria transmission.

I propose that 'vector control' should refer, in this context, to reduction of the mosquito population's vectorial capacity. The vectorial capacity of a population is defined as the average number of inoculations with a

specified parasite, originating from one case of malaria in unit time, that the population would distribute to man if all the vector females biting the case became infected. This definition, from Garrett-Jones and Grab (in the press), is an attempt to give more precision to one published by me in an earlier paper[1]. Vector control is epidemiologically effective when the vectorial capacity is such that a declining rate of transmission, leading to its interruption, can be predicted.

Vectorial capacity in this sense may be assessed as the product of three parameters: (*a*) *the man-biting rate*, representing the incidence of biting-contact between the mosquito and the people in terms of number of bites per person per night; this indicates the average number of vector females liable to become infected per case per day; (*b*) *the expectation of infective life*, or days of infective life per mosquito infected with the given parasite species; (*c*) *the man-biting habit*, or bites on man per day per individual female.

Table 1 illustrates degrees of control of a vector population having a natural man-biting rate of 10, man-biting habit of 0·25, female daily survival rate of 0·9 and transmitting *P. falciparum* with 12-day sporogony.

Table 1

	Proportion surviving per day	Man-biting rate (bites)	Expectation of infective life (days)	Man-biting habit (bites)	Vectorial capacity (inoculations)
Pre-attack	0·9	10·0	2·68	0·25	6·70
Attack:					
(*a*)	0·8	4·72	0·308	0·25	0·364
(*b*)	0·7	2·96	0·0388	0·25	0·0287
(*c*)	0·7	1·48	0·0388	0·125	0·0072

Three possible situations soon after spraying are shown, that is, before there has been time for output from the breeding-places to be affected. In lines (*a*) and (*b*) the indicated reductions in daily survival entail the reductions shown in the man-biting rate and expectation of infective life (life beyond 12 days from time of infection); hence the much sharper reductions in vectorial capacity. Line (*c*) postulates a halved man-biting habit (by deviation to animals, as may be common in sprayed areas) superimposed on reduced longevity. This, by halving also the man-biting rate, reduces vectorial capacity by a further 75 per cent. (From any given birth-rate the density of a population with constant mortality through life varies as its expectation of life. Hence, a mosquito's man-biting rate may be expected to vary directly as the female's expectation of life. For example, when the proportion surviving through one day is reduced from 0·9 to 0·8 the expectation of life is thereby reduced from 9·49 to 4·48 days[1] (Garrett-Jones and Grab, *Bulletin of the World Health Organization*, in the press), with the immediate result that the density and the man-biting rate are reduced proportionately. The relevant mathematical formulæ are given by Macdonald[3] and by Garrett-Jones[1].)

In terms of epidemiological effectiveness, in situation (*c*) the unit source (that is, the infective malaria case) could give rise to about one infective bite per 140 days (1/0·0072), which is probably below the critical malaria reproduction level even where most cases remain untreated. In (*b*) there could be one infective bite per case per 35 days, long enough to detect and treat most cases in a malaria-eradication programme. Ineffective vector control is represented by (*a*), where the source could give rise to an infective bite about once in three days.

In any given environment and situation (such as one of those postulated here), the vectorial capacity for *P. vivax* of a mosquito population fully receptive to infection is necessarily greater—and its degree of reduction by vector control is less—than for *P. falciparum*, owing to the quicker sporogony of *P. vivax*.

Where two or more vector species occur, their joint potential for transmitting a given parasite is equal to the sum of their vectorial capacities. This potential rate of transmission, which has been called the parasite's 'daily reproduction rate'[1], refers to the potential number of infections distributed *per case per day*, in contradistinction to the basic reproduction rate which refers to the potential number distributed *per case*[3,4]. (An example of how the basic reproduction rate may be calculated is cited from Macdonald[3] by Pampana[5]. The assumed situation is that postulated in line 1 of Table 1, except that the vector's man-biting habit is given as 0·5. In those circumstances the basic reproduction rate, from a case infective for 80 days, is shown to be about 1,120—thus: $10 \times 2{\cdot}68 \times 0{\cdot}5 \times 80 = 1{,}072$.)

Vectorial capacity is a characteristic of a mosquito population related to the ecological conditions, and may be assessed irrespective of whether any cases of malaria are present at the given place and time. It thus differs radically from the sporozoite rate, the 'average infective density', or any other index of vector efficiency as defined by the World Health Organization[4]. Obviously, in any malarious area the vector's vectorial capacity will be subject to natural variations (according to relative density, longevity and man-biting habit); before the start of an attack on malaria these variations might be assessed to reveal, not the month of maximal transmission, but the month of steepest upward trend in transmission (which must happen somewhat earlier in the season). Then, when the vector is subjected to a fixed régime of control, assessments of its vectorial capacity might indicate whether the trend of transmission is consistently downwards or takes an upward turn in certain localities and in certain months. Finally, when no known malaria cases remain, knowledge of the mosquito's vectorial capacity may give warning of where and when there is danger of transmission becoming re-established, in the event of the importation of one or more cases.

It is submitted, therefore, that the probability of achieving interruption of transmission in a given area by means of the anti-mosquito measures in force, and, afterwards, the risk of resumption of transmission in that area, should be judged by the same type of criterion—the daily reproduction rate, assessed through the mosquito's vectorial capacity. The criteria for assessing the probability of interruption and of resumption of transmission were discussed by the WHO Expert Committee on Malaria at its eleventh meeting (Geneva, 1964). It is anticipated that these matters will be dealt with in the Committee's report (World Health Organization, in the press).) The resulting advantage in the continuity of entomological approach to assessment, in the successive phases of eradication, needs no stressing.

The problems of assessing vectorial capacity in field practice are essentially ones of sampling and of scale. Direct biting-catches on human baits probably offer the best hope of estimating the average incidence of contact between the vector species and the people. But the great variability of that contact would seem to dictate that the sampling be repeated on several nights per month, using a large group of human baits, extending the catches through the whole of the mosquito's biting cycle and to those stations (indoor and/or outdoor) where the people are to be found at each period. These problems are discussed by me in an unpublished WHO document (*WHO/Mal/*450).

Estimation of the expectation of infective life involves observations on the proportion of a sample surviving in Nature over a known interval of days. As the technique of counting the dilatations in the ovariole is still too difficult for routine application to tropical vectors, it is more usual to determine the proportion of parous females. The technique of Detinova[6] is gaining increasingly wide application. However, it is important to sample the population in such a way that the mean difference in age between the nullipars and the primipars in the sample is ascertainable. If females caught biting man are used, as advocated by Hamon[7] and other workers, it often appears justifiable in warm climates

to take this interval as equivalent to three days. Samples thus caught in ovarian stages I and II are rapidly dissected to determine the proportion with uncoiled tracheolar skeins on the ovaries. The computation of the expectation of infective life from these data is discussed by Garrett-Jones and Grab (in the press).

Finally, the man-biting habit is itself compounded of the frequency of feeding and the human blood index of the mosquito[3]. The former has often been equated with the gonotrophic cycle, but this appears to need further study in many areas. Accurate assessment of the proportion of blood meals containing human blood in a given sample is carried out by the Lister Institute, England, in collaboration with the World Health Organization[5]. On the other hand, the unbiased sampling of blood meals in the field presents rather formidable difficulties, as I have already shown[1]. The samples should reflect the day-time distribution of the blood-fed females, but often we do not know the distribution of the types of resting place, let alone that of the mosquitoes. In sprayed areas the problem is still worse, since indoor-feeding mosquitoes may die before the daytime samples are collected, and then no form of diurnal sampling of survivors can fully represent the feeding population of the previous night. This problem merits urgent investigation in view of the probability that DDT and other insecticides may reduce vectorial capacity by diverting the mosquitoes to animals as well as by killing them.

In various malaria-eradication projects increasing attention is being given to the measurement of one or more of the factors determining vectorial capacity. Sustained attempts to evaluate all the factors together have been made at a few places, for example, in the Bobo-Dioulasso District of Haute Volta, where spraying with DDT failed to interrupt transmission of *P. falciparum* by *A. gambiae* and several associated vectors[2]. Yet it is true to say that nowhere, as yet, has an investigator combined his results with the view of estimating (without reliance on the sporozoite rate) the vectorial capacity of the mosquito populations under study. Neither has the daily reproduction rate of malaria—referring to the potential incidence of new infections per existing case per day—been considered in its bearing on the prognosis for interruption of transmission by the use of residual insecticides.

Despite the difficulties alluded to, it should be a primary concern of malaria entomologists to assess vectorial capacity and evaluate the resulting epidemiological trend. It is an assessment deserving priority as an operational criterion of insecticidal attack. Moreover, the problems involved constitute as strong a scientific challenge as may be encountered in most laboratory research. This fact, considered together with the epidemiological importance of the assessment, justifies the recruitment by malaria-eradication services of well-qualified scientists, and requires that they be carefully trained for these specialized entomological duties.

THE CHINESE WATER-BALANCE ESCAPEMENT

BURSTALL, Lansdale and Elliott[1] described the third of a laboratory series of water-wheel models of the mechanical escapement in Su Sung's clock, and expressed their belief that it represented the system used in the Chinese original of the eleventh century. From consideration of the nature and performance of the original I cannot agree that the representation is adequate.

Needham *et al.*[2,3] showed that the escapement wheel of A.D. 1088, 11 ft. in diameter, drove an assembly of heavy time-indicating and astronomical machinery. This comprised two vertical shafts about 15 ft. and 20 ft. long, six or eight pairs of gear-wheels including two or three separate solar-to-sidereal time-conversion trains, six jack-wheels over 6 ft. diameter carrying calendar-work and 150 time-indicating jacks, a 4½ ft. diameter celestial globe, and an observational armillary sphere with a 6 ft. diameter bronze rotating component which itself weighed over 150 lb.

It has been shown elsewhere[4] that there was one escapement action every 24 sec. At each action static friction had to be overcome, and the escapement wheel and machinery accelerated from rest; work had then to be done in movement against friction and the resistance of the striking mechanisms and other jack-work. Motive power was supplied by a regular flow of water at not more than 25 lb./min entering the buckets of the water wheel near its horizontal diameter. Even if a conversion efficiency of 100 per cent could be achieved in the water-wheel, an average power of only about 1/25 h.p.—28 watts—would be available for work. Yet the first laboratory model of Burstall *et al.* was designed to spill the water from each one of its eight fixed buckets as soon as the wheel moved[5,6]; and although not shown in their Fig. 1 a similar arrangement was evidently relied on in the third model to allow the 36-compartment wheel to reciprocate as described[1].

My assumption that in reality the 36 buckets emptied lower down the wheel is supported by the fact that a receiving vessel 11·4 ft. long[12] was provided to catch the water, and was positioned to extend below the entire lower half of the wheel.

The timekeeping of the water-balance escapement was such that Su Sung[7] was able in his astronomical chapter[8] to give data of the Sun's apparent position, in relation to the quasi-sidereal rotating co-ordinate system of the armillary sphere, with a precision of ± 1/16th of a Chinese degree of arc. This implies the maintenance, at least over the period between one sunset, sunrise, or noon observation and the next, of a time-keeping accuracy within ± 15 sec, which is consistent with the choice of a 24-sec time unit for the escapement, and with Su Sung's interest in the 'hurrying and dawdling' of the Sun in its annual circuit.

Good timekeeping depended on accurate determination of the time unit of 24 sec by division of the regular flow of water into equal portions of not more than 10 lb. successively in each bucket. The weighing operation must surely have been done under excellent conditions, but the models of Burstall *et al.* have provided for measuring only the variable small net force likely, under real conditions, to be exerted on an external balance-lever by a rigid water-wheel, while in the act of initial movement against the static friction of all the machinery. It seems to me that even if the original escapement could operate at all on this system, it would have been unlikely to keep good time.

A practical reconstruction, avoiding the difficulties of a rigid water-wheel and providing a truly chrono-

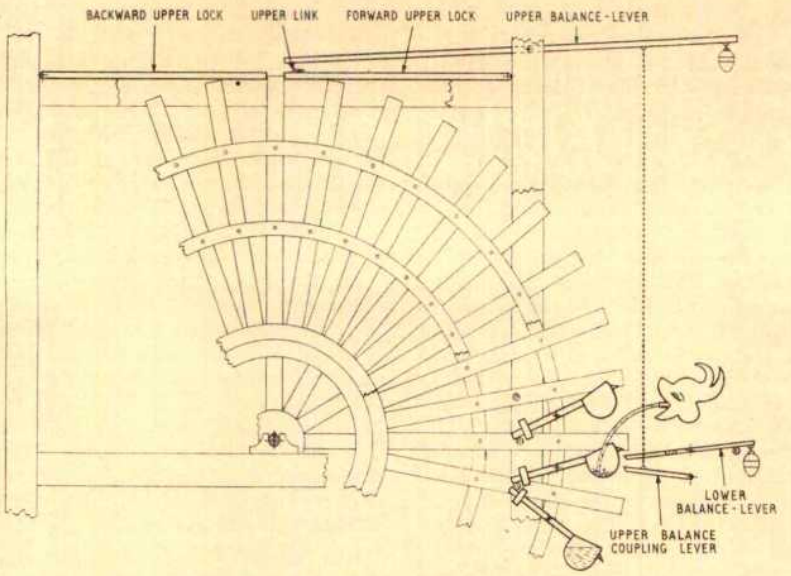

Fig. 1. Diagram of the escapement, as reconstructed

metric motion, was described[4] and demonstrated[9] in 1962. Fig. 1 is a diagram of the escapement mechanism, for comparison with that of Burstall *et al.* Fig. 2 is a photograph of a more recently constructed 1 : 6 scale working model of the original escapement, made, except for the outer framework, as nearly accurate as was conveniently possible on this scale. This model operates with the correct 24-sec time-unit cycle, by gravity feed of water from a true-to-scale constant-head tank fed by an electric pump. It would certainly be capable, when reproduced at full size, of doing all the work of the original while keeping time with an accuracy of at least about the right order. A model similar to this, but in more durable materials, is under construction for the new horological gallery of the Science Museum, South Kensington, and another, at 1 : 5 scale, for Historisches Uhren-Museum Wuppertal. This reconstruction has remained unchallenged by technical criticism since its publication, and has been stated by Dr. Needham to include nothing that the text does not authorize when fully understood[10].

According to the translation of Needham *et al.* the original escapement wheel had "seventy-two spokes and thirty-six scoop-holders mounted on the three reinforcing rings of the wheel"[11], and "each holder grasps a scoop, of which there are thirty-six in all"[12]. Needham *et al.* commented: "The scoop-holders are not described in detail but they were probably a simple shelf fixed to a spoke on either side"[13], but this did not appear to me to account for their being mounted on the reinforcing ring or rings. The 1962 publication[4] showed how practical consideration of the need to weigh each scoop separately from the wheel led to the suggestion that the scoop-holders, *hung* (radical 85 plus 6 strokes, signifying 'extensive' etc. in modern usage[14]), were supporting levers for the scoops, pivoted to the outer reinforcing ring, positioned by stops perhaps, as in the Fig. 2 model, fixed to an inner ring (not shown in Fig. 1), and counterweighted for slightly more than the tare weight of the scoops. This suggestion led, with a minimum of further experiment, directly to a successful reconstruction of the escapement. Dr. Needham tells me that a re-examination of the Chinese text, kindly carried out by him with the collaboration of Dr. Lu Gwei-Djen, has confirmed that it contains nothing which requires retention of the natural first assumption that the scoops and their holders were fixed rigidly to the wheel.

Burstall *et al.* do not mention scoop-holders, or spokes. The use of fixed water-compartments has led them to devise an 'interrupter cam' to permit a reciprocating motion of the wheel in their third laboratory model[1]. The textual difficulties which this 'interrupter cam' presents are mentioned later; apart from these it appears unlikely that the very light lower balance-weight, of say 5 lb. at most, which is all that a rigid wheel would possibly allow under real conditions, could have ensured backward rotation of the wheel against the resistance of the machinery, even if all the water-compartments were empty. Furthermore, Su Sung states that arrangements were made in the original to prevent any recoil of the wheel after the sudden arrest of its forward driving stroke. The relevant passage was translated by Needham *et al.* as follows: "After each scoop has so fallen, the stopping

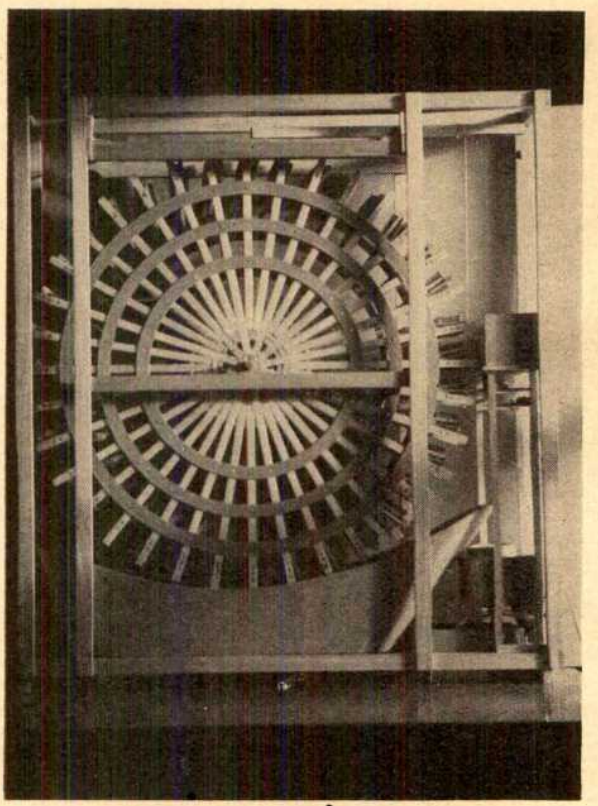

Fig. 2. Water-driven 1 : 6 scale model of the escapement

and locking device resists once again the next scoop, but since this might cause the wheel to recoil counter-clockwise, the right-hand (left as seen from the front) upper lock (that is, the ratchet action) acts to prevent any such movement"[15]. To avoid the seeming confusion of 'right' and 'left' in this account the part in question has been designated the 'backward upper lock' in Fig. 1.

Corresponding to the 'backward upper lock' but on the other side of the wheel, Su Sung's illustration[29] shows another 'upper lock' which has been designated 'forward upper lock' in Fig. 1. His text refers to both of the 'upper locks', and to their pivots on the escapement framework. Needham *et al.* mentioned that they had omitted the second 'upper lock' from their tentative theoretical reconstruction for simplicity. It has been omitted from the models of Burstall *et al.*, though their third model[1] shows a vestigial trace of it in the form of the 'limit stop H', which appears to have originated from a conjecture by Needham *et al.*, made before the real nature of the 'forward upper lock' had been established[16,17]. In reality, as explained by Su Sung, both 'upper locks' rested on the horizontal beam at the top of the escapement as shown in Fig. 1, and since the upper balance-lever could rest on the 'forward upper lock' there was no call for a separate 'limit stop H'. The relevant passages were translated by Needham *et al.* as follows: "Two upper locks, one on either side, are put to the left and right between the main posts, lying on the beam and controlling the even movement of the great wheel"[17] and, elsewhere, "There are two upper locks, one at the left, another at the right; at the end of each a shutting axle (discussed later) is attached. These two shutting axles are attached to the main posts (of the framework) at either side. They face each other on the left and right to stop the scoop-holders, *hung*, of the great wheel" (ref. 18). The text actually has not *hung*, but *fu* (spokes—radical 159 plus 9 strokes). It was the 'forward upper lock' which took the full impact of the wheel-spoke at the end of each driving stroke, and then held the load until lifted by the upper balance-lever at the correct instant for release 24 sec later. The 'backward upper lock' similarly had to take the impact of any recoil. This is why both 'upper locks' were pivoted to main vertical members of the framework.

As explained in 1962[4], it was found by experiment essential, for effective release of the 'forward upper lock' from the load of the wheel-spoke, to arrange for kinetic energy to be stored in the 'upper balance-lever' during the movement of the 'upper balance coupling lever' under the weight of the full scoop released by the 'lower balance-lever'. For this purpose, the 'upper balance-lever' was connected loosely to the 'forward upper lock' by the short length of chain designated 'upper link' in Fig. 1. In the absence of a 'forward upper lock' in their models, Burstall *et al.* followed the tentative reconstruction of Needham *et al.*[3] in the provision of a buffer or 'upper stop' fixed to the end of the 'upper balance-lever', where according to Su Sung's illustration[29] and text the 'upper link' hangs. This arrangement can now be shown to be the result of a pardonable misunderstanding of an eleventh-century Chinese technical term (see refs. 19 and 20).

In accordance with prevalent modern usage, Needham *et al.*[21] translated the character *kuan* (radical 169 plus 11 strokes) as 'stop' in *t'ien kuan* 'upper stop' and *t'ien hêng kuan* 'upper balance stop', as 'stopping' in *t'ien (hêng) kuan shê* 'upper (balance) stopping tongue', and as 'shutting' in *kuan chu* 'shutting axle'. This last example particularly aroused my technical curiosity and led eventually to the discovery of a previously untranslated passage in Su Sung's first chapter, in which he refers to his newly invented system for rotating the quasi-sidereal co-ordinate component of the armillary sphere by means of the *t'ien chu kuan lun* 'upper shaft coupling wheel'[22]. Clearly neither 'stop', 'stopping', nor 'shutting' will do for *kuan* here. With this clue, it became evident that amendment to 'coupling', or 'link' would at once make better sense where *kuan* appears elsewhere in illustration and text, and would agree with the practical need shown by experiment with the model escapement (see also refs. 23 and 24).

The suggested amendment may be considered to strengthen the slight textual evidence towards acceptance of practical arguments[25] for thinking that the water-balance escapement, substantially as now reconstructed, was that used by Chang Hêng for driving his astronomical apparatus in the second century[26].

Finally, it is to be noted that the 'star-shaped gadget'[16] which was elaborated by Burstall *et al.*[1] in their third laboratory model into an 'interrupter cam' for allowing the wheel to reciprocate, was identified and illustrated by me in 1962[4] as the horned dragon's head gargoyle (compare Fig. 1) traditionally used through many centuries to ornament the outflow pipes of Chinese water-clocks[27,28]. The illustration in the 1922 Chinese octavo reprint of Su Sung's book[29], and the better print in the Chinese quarto edition of 1844, reveal what—though at first sight designated 'checking fork'—may well be the outflow pipe itself, depicted as a square prism projecting from the dragon's mouth, on an alignment independent of that of the visually adjacent lower balance-lever, and corresponding to the form in which the artist depicted the outflow pipe from the upper flume of the water-raising machine in another illustration[30]. The (double) 'interrupter cam' of Burstall *et al.* needed additional features for which authority of both text and translation is lacking.

We welcome the opportunity of commenting on that part of Mr. Combridge's paper concerned with our recent article[1], for he makes some astonishing assertions about the working models he has made to represent Su Sung's escapement, and they should not go unchallenged. We do not consider that his models represent the mechanism described in the original Chinese text, whereas the model we described gave what we believe was the first explanation (backed by experiment) of how a water-wheel

escapement with fixed scoops or buckets as described by Needham, Wang and Price[2] could have been made to operate.

It was Mr. Combridge's failure to see how this could be done that led him to mount the thirty-six scoops on thirty-six pivots around the wheel, each scoop having a separate counterweight and stop.

The important difference of principle between the Combridge models and ours can be summarized thus. In the Combridge models the great wheel is held rigidly by the two upper locks while each scoop is filled. The scoops moving on their individual pivots are the essential elements of the escapement, for the wheel is then being held stationary just as if it were part of the structure. Meanwhile, the lower balancing lever (which we regard as an essential element of the escapement) is doing nothing —just resting on a stop that is not mentioned in the original text. The scoop is positioned partly by the upper lock, against which a spoke of the great wheel must rest all the time because some water remains in all the scoops in the lower right-hand quadrant in the Combridge models. Accordingly it seems to us that the lower balancing lever in these models has become practically redundant; it does no more than break the fall of the scoops on their pivots and, if the various balance weights in the mechanism were suitably adjusted, it could be dispensed with altogether.

In our Mark III model, on the other hand, the great wheel itself is the scape wheel of the escapement, which is somewhat similar to a modern anchor escapement in that the forward movement of the wheel is restrained at all times by the lower balancing lever with which one of the scoops is always in contact, except at the moment of tipping. Forward over-run is prevented by the upper stop (or lock) and backward over-run by the back upper stop against which the wheel rests when the scoops are emptied.

In our model the weighing of the water in each scoop is effected, as it were, by two weighbridges—one the great wheel itself carrying the scoop being filled and the other the lower balance lever. The same two pivots are in use the whole time; they are (1) the bearings of the great wheel and (2) the pivot bearings of the lower balancing lever. In the Combridge model, thirty-six pivot bearings are involved in the weighing in turn, and it seems inconceivable that if they existed on the original they should never have been shown in the illustrations or mentioned in the text when every other bearing was described.

We were surprised to read that Mr. Combridge now tries to explain away the absence of an upper stop on his models by challenging the accuracy of the translation by Needham, Wang and Price of the word *kuan*, asserting that it means coupling or link and not 'stop' as given in *Heavenly Clockwork*. On this point we have consulted Mr. A. C. Barnes, lecturer in the Chinese Language in the University of Durham, who has authorized us to state that in his opinion there is no other way of translating the word *kuan* in this context except by the word 'stop'. On good authority he considers it would be un-Chinese to translate it in any other way. This opinion has also been confirmed by a Chinese engineer, Dr. Tao Ching Hsu, of the University of Edinburgh.

We concede the objections to the interrupter cam as shown in our earlier article, but since it was published we have realized that the function being performed by the cam, that is, lifting the chain at the correct point in the cycle, can be performed more simply by the checking fork itself. All that is required is the addition of a third central prong to the fork, and this prong could be the star-shaped gadget itself, since it is illustrated in the right place in the original woodcut. Alternatively, the star-shaped gadget may be the horned dragon's head gargoyle, as Mr. Combridge suggests. We do not know. This modification disposes of all the four features for which the authority of the text was lacking. We have also, following a comment by Dr. Needham, added, on the right-hand side of the wheel, a second upper lock that is lifted by the overhead stopping lever. While this is redundant and plays no part in the operation of the mechanism, it was described in the original text, and was presumably added as a safety device in case the buffer stop became worn or damaged. With these additions it appears to us that the method of operation of our model now meets in every respect the description given in *Heavenly Clockwork* for the escapement of Su Sung.

We have just learned[4] that a reconstruction of Su Sung's clock is now on display in the Historical Museum in Peking and we look forward to learning what form of escapement is portrayed there. The author, Li Jen-yi, describes it as "employing the escapement principle now used in modern timepieces".

Burstall *et al.* and I were at one in seeing that the early theoretical reconstruction of Needham *et al.* would not work as it stood. We differ because our aims from there onwards have in fact not been the same.

Their aim has been to show that the reconstruction of Needham *et al.* can be made to work—under selected laboratory conditions and without a load—if various modifications and additions are made to it. Up to the present, they have produced in turn five different laboratory models. My aim was to deduce as accurately as possible from the published translation, considered as a whole, what the medieval Chinese engineers actually did and described in their own idiom. By a practical engineering approach, and some brief experiments, I arrived in 1961 at what I still believe to be a satisfactory conclusion, though without wishing to claim that it is incapable of further improvement.

It is not the fact that 'every other bearing was described'. There are almost no details, for example, of the internal mechanism of the jack-work and calendar-work. In assuming that the lower balance-lever in my reconstruction has become practically redundant and could be dispensed with altogether, Prof. Burstall has overlooked the explanation of the essential functions of the various parts. The function of the scoop-holder counter-weights (which might have been integral with the scoop-holders and so not mentioned separately) is to compensate for the *tare* weight of the scoops, so (*inter alia*) preventing them contacting the checking fork while being brought into position before filling. The function of the lower balance-weight was to support almost the whole net weight of the water in the scoop, and at the correct instant to release the full scoop suddenly on to the upper balance coupling tongue (or lever) for maximum speed and effectiveness of action of the release mechanism.

The backstops for the lower balance-lever and trip lever (upper balance coupling lever) are formed by the horizontal bars between the legs of the stand for the constant-head tank, which are illustrated and referred to by Su Sung. In my scale models they appear as functional members in the correct position as illustrated.

Dr. Needham, who has seen the Peking 1958 model recently, confirms my assumption[1] that it does not work.

LETTERS TO THE EDITOR

COSMOLOGY

Gravitational Collapse

RECENTLY there has been renewed interest in the ultimate fate of the gravitational collapse of large masses. From the early work of Chandrasekhar[1], Oppenheimer and Volkoff[2], and the more recent work of others[3], it is clear that for a relativistic gas there is a critical spherical mass of $M_c \sim 1\ M_\odot$, where $M_\odot$ is the mass of the Sun. In any relativistic degenerate mass of $M > M_c$, no matter what radius it has, the gravitational field everywhere exceeds the outward force exerted by the pressure gradient. No static equilibrium configuration is possible, and hence the mass continuously collapses.

There is nothing in the present theories of the structure of matter which can arrest the collapse of such a mass once it has started. This can be shown by comparing the relative strengths of the strong and gravitational interactions. If $g^2/\hbar c \sim 15$ and $Gm_n^2/\hbar c$ are the coupling constants for the strong and gravitational interactions ($\hbar$ is Planck's constant, c the velocity of light, G the gravitational constant, and m_n the nucleon mass), then:

$$\frac{g^2}{\hbar c} \sim 10^{39}\,\frac{Gm_n^2}{\hbar c} \qquad (1)$$

In a spherical mass consisting of N nucleons packed closely together the short-range strong interactions between the nucleons account for a total energy of the order Ng^2/λ, where λ is a characteristic distance over which these interactions are effective. The gravitational interactions, however, which are usually regarded as being very weak, are long-range and their total energy is of the order $GN^2m_n^2/R$, where R is the radius of the mass. In such a system the gravitational interactions predominate when:

$$GNm_n^2/R > g^2/\lambda \qquad (2)$$

Since $N \simeq R^3/l^3$, where l is the internucleon distance, it follows from (1) that this inequality is equivalent to:

$$N > 10N_\odot(l/\lambda)^{3/2} \qquad (3)$$

where $N_\odot \sim 10^{57}$ is the number of nucleons in a solar mass. This extremely crude calculation shows that in a dense and massive body it is possible for the strong interactions to be relatively weak compared with the gravitational interactions. At nuclear density: $l \sim 10^{-13}$ cm, and λ is of the same order for the pion Compton wavelength. Even if, at higher densities, the field quanta interacting with the baryons account for almost the entire mass of the system, the ratio l/λ cannot exceed unity, and once the collapse commences the nuclear repulsion is always crushed by gravitation.

The startling possibility of a complete gravitational collapse encounters an apparent dilemma when one considers the exterior space-time metric of such a mass. For a spherical body of mass M the exterior metric is given by Schwarzschild's solution:

$$ds^2 = (1 - r_s/r)c^2dt^2 - (1 - r_s/r)^{-1}dr^2 - r^2d\theta^2 - r^2\sin^2\theta d\varphi^2 \qquad (4a)$$

$$r_s = 2MG/c^2 \qquad (4b)$$

By Birkhoff's theorem[4] this metric applies independent of the rate of collapse of the spherical mass. The co-ordinate intervals dt and dr are the proper time and distance intervals for observers at very great distances. The radius r_s is the Schwarzschild singularity which, for an external observer, sets a lower limit on the size of the collapsing mass. For a massive body like the Sun this limiting radius is of the order 1 km.

Consider two separate systems of reference. The first or external system is at a co-ordinate distance r_1 where the proper intervals of time are:

$$dt_1 = (1 - r_s/r_1)^{1/2}dt \qquad (5a)$$

The second or co-moving system is at the surface of the contracting mass which has a diminishing co-ordinate radius r_2; in this system the proper intervals of time are:

$$dt_2 = \left(1 - \frac{r_s}{r_2}\right)^{\frac{1}{2}}\left(1 - \frac{v^2}{c^2}\right)^{\frac{1}{2}}dt \qquad (5b)$$

where v is the radial velocity of the surface relative to a local observer at rest. Thus as $r_2 \to r_s$, the time-interval dt_2 in the co-moving system becomes infinitely dilated compared with dt_1, in the external system, and vice versa, the time-interval dt_1 becomes infinitely contracted compared with dt_2. In the limit, a short moment of time in the history of the co-moving system is equivalent to an infinite duration in the history of the external system. For an observer in the external system the Schwarzschild singularity is undoubtedly real, since it requires an infinite amount of his time for the collapsing mass to attain the radius r_s. In the co-moving system this singularity does not exist. As an example, consider a free-fall collapse of a body in which the pressure is zero and the density is uniform. The internal metric is isotropic and homogeneous and it is found that it takes approximately 1 h in the co-moving system for a solar mass initially the size of the Sun to attain a radius of r_s. The time taken to collapse from the Schwarzschild radius to a point singularity is:

$$\tau_m = \frac{2r_s}{3c} = \frac{4GM}{3c^3} \qquad (6)$$

and for a solar mass this is of the order of 1 μsec.

The following question must therefore be asked. Since the time taken for collapse to the Schwarzschild radius is infinite in the external system, is it meaningful to consider the ultimate fate of gravitational collapse in massive bodies? It will now be shown that the answer depends on the nature of the universe.

As the radius r_2 of the collapsing mass approaches the Schwarzschild radius r_s, the entire future history of the distant system occurs during a short period of time in the co-moving system. In a universe which continuously expands this history contains, for the purpose of this discussion, nothing of any particular interest, and the answer to the foregoing question is that collapse beyond the Schwarzschild radius is meaningless for an observer in an external system. At present the universe is expanding and there is no need, therefore, to consider the ultimate fate of gravitational collapse in a continuously contracting universe. However, the universe may be oscillating, and in that case its present period of expansion will be followed by a period of contraction. In this type of universe the future history of the external system contains an event of profound importance. During the given short interval of time in the co-moving system the universe expands and then contracts. During the final state of its contraction the entire universe assembles around the collapsing body, and the collapsing body then falls into a point singularity in company with the rest of the universe. Thus the original external system and the original co-moving system both participate in the final collapse. A Schwarzschild singularity is physically real only for an external observer, but in the final state of collapse of the universe all observers are co-moving and are on an equal

footing, and there is no infinite dilation or contraction of one interval of proper time with respect to another. Consider, for example, an oscillating universe in which the pressure is negligibly small and the density is uniform. The time taken in the final stage to collapse from a density ρ_u to an infinite density is:

$$\tau_u \simeq \frac{2}{3}\left(\frac{3}{8\pi\rho_u G}\right)^{\frac{1}{2}} \quad (7)$$

By setting $M = 4\pi\rho_m r_s^3/3$ in (6), where ρ_m is the density of the collapsing body, it is seen that the time of collapse, τ_m, of the body and the time of collapse of the universe, τ_u, are equal when ρ_u becomes equal to ρ_m. This means that a solar mass in free-fall gravitational collapse becomes part of the collapsing universe in the last microsecond of its career. Such a universe can presumably oscillate indefinitely: it emerges from the singular state, innumerable bodies collapse asymptotically to their Schwarzschild radii, these singularities are swept up and smoothed out as the universe returns to its singular state, and finally it re-emerges to commence a fresh cycle.

To the question: is it meaningful in an external system to consider the ultimate fate of a body that is gravitationally collapsing, the answer is: yes, if the universe is oscillating. For the external system itself participates in the final stage of the gravitational collapse.

Cosmological Red-shift

Hoyle[1] has shown that for a steady-state universe consisting of uniformly distributed matter of density ρ a metric of the form:

$$ds^2 = -dr^2\left(1 - \frac{8\pi}{3c^2}G\rho r^2\right)^{-1} - r^2 d\theta^2 - r^2\sin^2\theta d\psi^2 + c^2\left(1 - \frac{8\pi}{3c^2}G\rho r^2\right)dt^2$$

applies if it is assumed that a uniform creation of matter occurs.

From this metric Hawkins[2] has deduced an expression for a red-shift, arising in the absence of any galactic displacement, given by:

$$\frac{\Delta\lambda}{\lambda} = \frac{4\pi}{3c^2}G\rho r^2$$

I recently proposed[3] that a red-shift will occur in any model universe containing uniformly distributed matter if absorption or shielding of gravitational flux occurs on the cosmological scale, and will be given by:

$$\frac{\Delta\lambda}{\lambda} = \frac{2\pi}{3c^2}G\rho r^2$$

which differs by a factor of 2 from Hawkins's equation.

The purpose of this communication is to emphasize the fact that the very different initial assumptions of either (*a*) the continuous creation of matter, or (*b*) the shielding or absorption of gravitational flux, both lead to similar results. Of perhaps greater interest is the fact that in neither of these approaches is the red-shift expression related quantitatively with the initial assumption. This would indicate that a still more fundamental relationship exists.

ASTROPHYSICS

Forbidden Lines from Atomic Sulphur

Forbidden lines from astrophysical and other sources are specially prominent from elements with an np^4 electron configuration. The best known are the auroral ($^1S_0$–$^1D_2$) and transauroral ($^1S_0$–$^3P_1$) lines of oxygen (OI). The present communication reports the laboratory excitation of the corresponding lines of sulphur (SI).

Conventional high voltage a.c. or d.c. discharges with positive columns were used. The tubes used varied in length from 12 to 200 cm, and in diameter from 1·5 to 3·0 cm. They were filled with xenon to a pressure of a few cm mercury after some sulphur had been distilled in, and were then sealed off and conditioned by passage of a current until impurities such as carbon monoxide had disappeared. With the smaller tubes local heating in the neighbourhood of the electrodes caused an increase in sulphur vapour pressure which tended to quench the forbidden lines, and limited the usable currents to less than about 1 m.amp. However, with the larger tube the intensity of emission was observed to be increasing even when currents as high as 15 m.amp were used. A detailed investigation of the excitation conditions is in progress.

Two spectrographs were used, a Recherches et Études d'Optique et de Sciences Connexes *HA* crossed grating instrument with a linear reciprocal dispersion of 3·5 Å/mm at 4600 Å and an aperture of *f*5, and a Huet *B*11 two-prism instrument which enabled the whole spectral range from 4000–8000 Å to be recorded on a single plate. The dispersion of the latter was 130 Å/mm at 7725 Å and the aperture *f*4. Kodak *OF*, II *L*, II *N* and 103 *aF* plates were used during the course of the investigation.

Using the large tube, with a current of 4 m.amp, it was found possible to record the lines in 4 min. The 4507 Å ($^1S_0$–$^3P_2$) line was not observed as it was obscured by a background of sulphur molecular radiation. It is hoped to record it using afterglow techniques.

Wave-length measurements were made using the xenon lines from the discharge as references. These measurements gave a wave-length of 4589·21 ± 0·05 Å for the $^1S_0$–$^3P_1$ transition and 7725·7 ± 1 Å for the $^1S_0$–$^1D_2$ transition. So far as we are aware, this is the first time the former line has been recorded.

These may be compared with the astrophysical value[1,2] of 7726·5 Å, and those computed from the accepted term values[3] of 4589·1 Å and 7724·4 Å.

We thank the Centre d'Études Nucléaires, Fontenay aux Roses, and the Observatoire de Paris, Meudon, for the facilities kindly granted during the course of the investigation. One of us (D. J. B.) also thanks the Ministry of Education, Government of Northern Ireland, for the award of a postgraduate studentship.

GEOPHYSICS

A Smooth Type of Cosmic Noise Absorption

Riometer investigations on auroral absorption events have been carried out so far by various experimenters in Alaska[1], Canada[2] and Scandinavia[3]. The characteristics of the auroral type of riometer absorption are normally given as follows: Auroral absorption is associated with the occurrence of visible aurora and magnetic disturbances. It is normally highly irregular in character, and although it may continue for a number of hours the individual peaks last only a few minutes.

However, there exists a special type of absorption event occurring occasionally during the local morning hours which is characterized by its very smooth shape. A typical example of such an absorption event is given in Fig. 1. As can be seen, the absorption at Kiruna increases very smoothly from the zero level (ionospherically quiet conditions) to a few decibels within 30 min. After reaching its maximum value, the decrease starts, which again shows a remarkably smooth shape, lasting approximately 1 h, after which time the undisturbed level is reached again. Another feature characteristic for those events is the obvious absence of any remarkable magnetic activity at the station where the absorption event is observed.

These two facts, namely, the smooth characteristics of the events and the absence of magnetic disturbances, could easily lead to the conclusion that such events might be small-scale proton events, as has also been assumed by Ansari[4]. These events seem, in fact, to be very similar to polar cap absorption (PCA) events, when observed at a single station. However, Ansari implies that they could not be PCA proton events, but leaves unanswered the question of where the protons are coming from.

All such smooth type absorption events which have been observed at Kiruna (geomagnetic latitude 65·3° N.) in 1962 (23 altogether) have been analysed in detail. All these events occurred in the morning during 0600–1000 h local time. As indicated here, the absence of any remarkable magnetic activity was evident during this period, for each of the 23 events investigated.

Fig. 2 is the reproduction of the S_D current system of an average magnetic storm according to Silsbee and Vestine[5]. It shows that during the local morning hours the current system changes direction. This is obviously the period during which the smooth absorption events occur.

The duration of the morning transition period of currents at Kiruna has statistically been investigated for 170 magnetic disturbed days. It was found that the interval during which the geomagnetic X-component variations were less than 80γ was always at least 2 h long (0700–0900 h local time). Furthermore, it was found that in all cases when riometer absorption of any kind was observed during this morning period no remarkable magnetic disturbances could be correlated.

On the other hand, magnetic stations situated at the night side of the Earth observed remarkable activity simultaneously. This wide-scale correlation has been found already in connexion with balloon-measured auroral X-ray fluxes by Kremser[6].

Riometer data from Cape Jones have been examined, this station being situated on the night side of the Earth when the smooth absorption events were observed at Kiruna. It was found that in all 23 cases typical auroral type of absorption (changing rapidly with time) occurred at Cape Jones around the times when smooth events were observed at Kiruna. Thus it is evident that absorption can simultaneously be observed on a large scale around the auroral zone which is most pronounced at a station situated at the night side and possibly occurring as strong

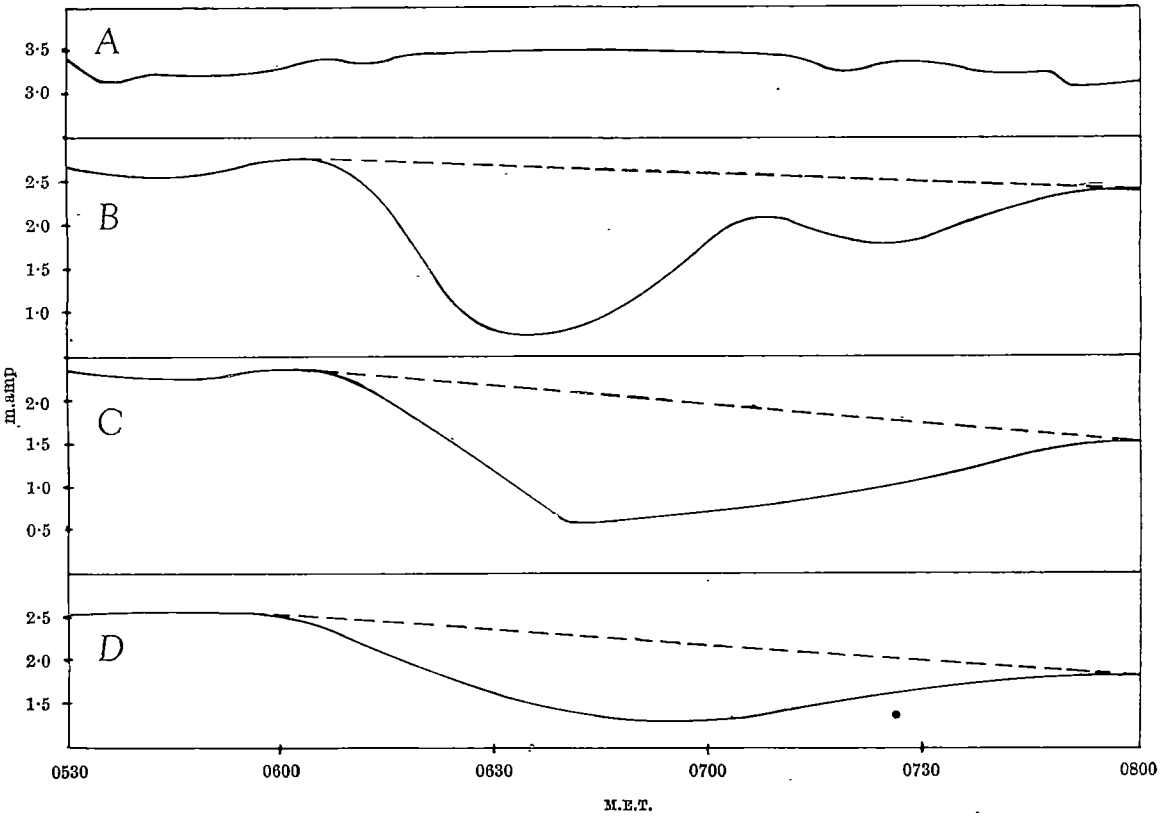

Fig. 1. Records of Scandinavian riometers for August 29, 1962. *A*, Longyearbyen (geom. lat. 74·1°); *B*, Tromsø (geom. lat. 67·0°); *C*, Kiruna (geom. at. 65·3°). Riometer frequencies all 27·6 Mc/s. *D*, Kronogård (geom. lat. 63·8°), riometer frequency 40·0 Mc/s. Broken rule indicates quiet day level

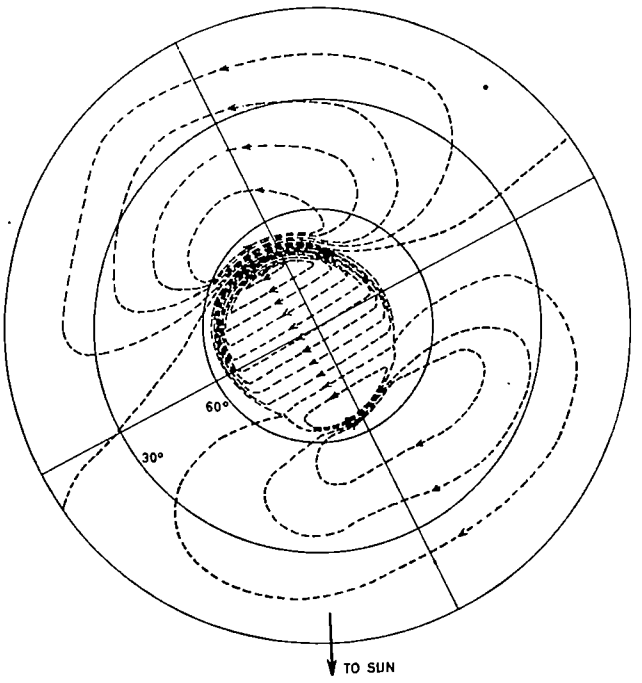

Fig. 2. S_D current system of an average magnetic storm (according to ref. 5)

absorption of smooth shape at a station situated on the morning side of the Earth.

Riometer data have been examined for the event of August 29, 1962, from Scandinavian stations situated at different latitudes, as shown in Fig. 1. It is evident that the smooth absorption event can only be observed at stations situated in or near the auroral zone. No absorption at all could be observed by the Spitsbergen riometers at Longyearbyen (geomagnetic latitude 74·1° N.). Unfortunately, there was no riometer operating south of Kronogård (geomagnetic latitude 63·8° N.) on this date. However, ionosonde data indicate that total blackouts were observed at auroral zone stations at 0700 and 0800 h local time. The f_{min} values were still increased at Lycksele (geomagnetic latitude 62·5° N.), whereas data at more southern stations did not differ from those observed on undisturbed days.

Another smooth absorption event, although much weaker in intensity, was observed on the following day, August 30, 1962. This event could only be recognized at Kiruna and Tromsø (geomagnetic latitude 67·0° N.), and not at Kronogård and Longyearbyen, that is, only at the stations situated well inside the auroral zone.

Thus, there seems to be very little evidence that the morning absorption events investigated for this work are caused by protons. Although these events show on riometer records a structure similar to PCA events, their occurrence is restricted to the auroral zone and to stations situated on the morning side of the Earth. The events analysed for this investigation did not occur during magnetically quiet periods, although no magnetic disturbances could be seen at Kiruna (the station where the smooth riometer absorption event was observed) due to the change-over of the S_D current system. Auroral (and magnetic) activity was observed simultaneously at stations located on the night side of the Earth. Balloon measurements by Brown and Barcus[7] seem also to indicate that electrons are causing the ionization responsible for this type of absorption. This is again emphasized in a recent publication by Brown[8].

Thus, it is concluded that these smooth events should be considered as belonging to the group of 'auroral type absorption events' caused by precipitation of energetic electrons.

Evidence of Whistler Guidance by Magneto-ionic Ducts of Poorly-defined Structure

The highly localized character of multiple whistler signals suggests strongly (though indirectly) that columns of field aligned ionization must exist[1–4]. In addition, simple ray tracing calculations show quite clearly that without these hypothetical columns a rapid dispersion in latitude would be observed following successive reflexions at conjugate magnetic field regions[5]. There is some direct experimental evidence[6] for the existence of these columns; but by and large, only column fragments seem to have been observed. Indeed, recent top-side probe measurements show no evidence for continuous columns[7].

In order to understand this apparent paradox an attempt was made to deal exactly with this very complex electromagnetic field problem. The magneto-ionic duct was represented as a cylindrical plasma, of uniform density, aligned with its axis parallel to a constant, uniform magnetic field, and immersed in an infinite, uniform plasma. Thus, a lossless, cylindrical, gyrotropic medium was immersed in an infinite, lossless, gyrotropic medium of different density. The physical constants of the two media bore a realistic relationship to those of the magnetosphere. Using the exact equations of the problem, a search was made for those modes which corresponded to trapping of the whistler energy within the cylindrical region.

Most of the general details relating to the theoretical analysis of this problem have already been worked out by P. Epstein[8] and M. A. Gintzburg[9]. Turning to the numerical details, the ducts considered (2–20 km diam) were immersed in regions having of the order of 10^4–10^5 electrons/cm^3 and ambient fields of 0·1–0·5 gauss. Whistler frequencies were chosen to be a few kc/s. The calculations were performed using an IBM 7040 computer.

A number of interesting and surprising results emerged. For example, with the angular dependence of the fields described by exp. (inθ), where θ is the azimuthal angle, it was found that trapping in columns of enhanced ionization occurred only for positive n; trapping in columns of reduced ionization occurred only for negative n. No trapping was found for $n = 0$.

Other, additional information relevant to whistler propagation was obtained. The radial decay constants, which describe the decrement of the fields in the transverse direction, were computed and tabulated for cases typical of whistler propagation. The results suggested that, if several columns of enhanced ionization, not too far apart, were present, whistlers could be trapped in the regions between these columns (by the process corresponding to trapping in columns of reduced ionization) as well as in the columns of enhanced ionization.

An investigation of the difference in density between a magneto-ionic duct and its surroundings, that was suffi-

cient to achieve trapping, developed evidence that density differences as small as 0·05 per cent are capable of supporting, and guiding without loss, a large number of modes. Indeed, a figure several orders of magnitude less than this now seems reasonable.

This result suggests very strongly that well-defined ducts are not necessary for whistler propagation; even though the density difference between a duct and its surroundings varies very greatly along a given field line—and the duct therefore appears to be broken—such variations have only negligible effects on the guiding and propagation of whistler signals.

Effect of Release of Compression on Magnetization of Rocks and Assemblies of Magnetic Minerals

Referring to the experimental results obtained by Kalashnikov[1,2] and Kapitsa[3] on reduction of magnetic susceptibility of rocks by their uniaxial compression, Stacey[4] has suggested that a possible local accumulation of mechanical stress within the Earth's crust in a pre-earthquake stage may result in an anomalous geomagnetic change of observable magnitude, which can serve as a pre-earthquake phenomenon for forecasting earthquakes.

The phenomenon of reduction of magnetic susceptibility by compression has been examined in more detail on assemblies of magnetites and titanomagnetites by Grabovsky and Parkhomenko[5], and these results have been theoretically justified by Kern[6] for the hydrostatic compression and by Stacey[7] for a special case. Experimentally, the fact has been confirmed as a part of results of our work on piezomagnetic phenomena of rocks and assemblies of magnetic minerals, as shown in Fig. 1.

It must be remarked, however, that the dependence of susceptibility on compression (P) obtained by Kalashnikov and Kapitsa, as well as by us, was measured under the condition that a magnetic field (H) is applied on a sample which has already been under the effect of compression. It may be considered, on the other hand, the local accumulation of mechanical stress within the Earth's crust occurs in the presence of the geomagnetic field (H). The magnetization in the former case is written here as $J(P,H)$ and that in the latter case as $J(H,P)$. Then our experimental results show that $J(H,P) > J(P,H)$.

Fig. 2 illustrates an example of magnetization curves of a sample of titaniferous magnetite under different experi-

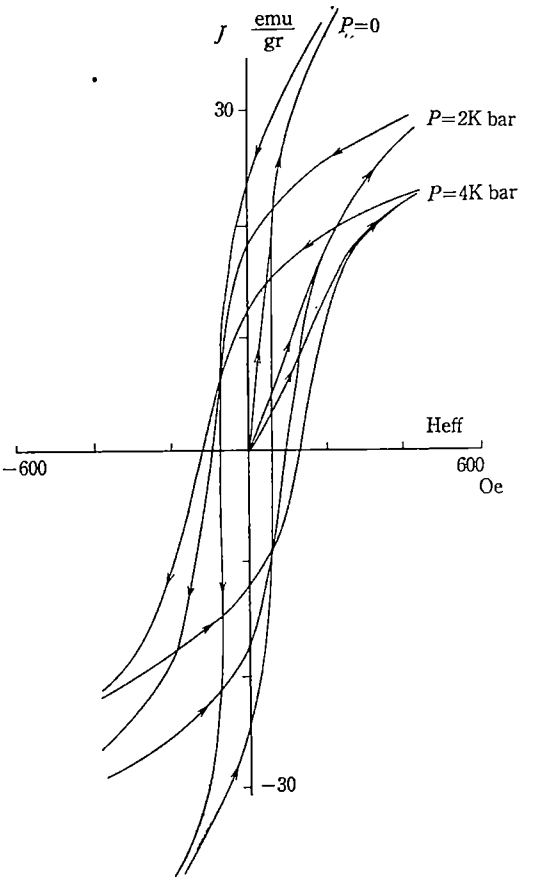

Fig. 1. Magnetic hysteresis curves of titaniferous magnetite under uniaxial compression P parallel to magnetic field H

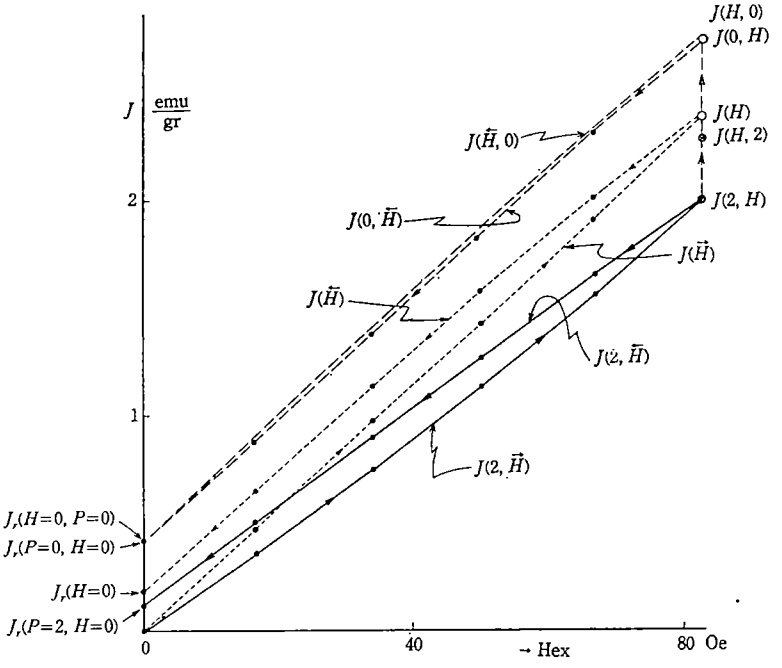

Fig. 2. Magnetization curves of titaniferous magnetite. $\vec{J(H)}$, magnetization with increasing H in $P=0$; $\overleftarrow{J(H)}$, magnetization with decreasing H in $P=0$; $\vec{J(2,H)}$, magnetization with increasing H in $P=2$ kbar; $\overleftarrow{J(2,H)}$, magnetization with decreasing H in $P=2$ kbar; $\overleftarrow{J(H,0)}$, magnetization with decreasing H after releasing P from $J(H,2)$ in $H=80$ œ; $\overleftarrow{J(0,H)}$, magnetization with decreasing H after releasing P from $J(2,H)$ in $H=80$ œ; $J(H,2)$, magnetization after compressing $J(H)$ in $H=80$ œ

mental conditions. The curves $J(\vec{H})$ and $J(\overleftarrow{H})$ represent respectively magnetization curves for increasing and decreasing values of H in case of no compression. The point indicated by $J(H,2)$ represents the value of $J(H,P)$ where P denotes a uniaxial compression of 2 kbar along H. The compression of a sample already magnetized in H results in a decrease of magnetization. The point indicated by $J(H,0)$ represents the magnetization after releasing P in H. By releasing P, the magnetization jumps up from $J(H,2)$ to $J(H,0)$. The curve $J(\overleftarrow{H},0)$ shows the magnetization curve with decreasing H after releasing P. It is seen that the remanent magnetization $Jr(H = 0, P = 0)$ in this case is larger than that of the ordinary isothermal remanent magnetization, $J(H = 0)$. The curve $J(2,H)$ represents the magnetization with increasing H under the effect of $P = 2$ kbar. The magnetization $J(2,H)$ is definitely smaller than $J(H,2)$ for the same field; namely, $J(H) > J(H,P) > J(P,H)$, and consequently $J(H)-J(H,P) < J(H)-J(P,H)$.

By releasing P in H, the magnetization jumps up from $J(2,H)$ to $J(0,H)$, which is approximately equal to $J(H,0)$. Therefore, $J(0,H)-J(P,H) > J(H,0)-J(H,P)$.

From these results, one may conclude that: (*a*) the reduction of magnetization by compression in a magnetic field, that is, $J(H)-J(H,P)$, is much smaller than the value expected from Kalashnikov–Kapitsa's experiment on $J(P,H)$; (*b*) a sudden release of compression causes an abrupt increase of definitely larger amount in magnetization. Therefore, we consider that the reported local geomagnetic change between before and after an earthquake[4,5] may be mostly caused by release of stress at the time of earthquake occurrence.

[8] Kato, Y., *Sci. Rep. Tohoku Imp. Univ.*, **27**, 1 (1938).

In the preceding communication Nagata and Kinoshita report that the effect of stress on rock magnetization is, in many cases, only partly reversible. It should be pointed out that susceptibility changes reversibly with stress and that the irreversibility is a property of remanent magnetization only. But any process by which a magnetic material acquires remanence must be irreversible in the thermodynamic sense. The vital question raised by Nagata and Kinoshita is: does this irreversibility invalidate simple calculations of the seismomagnetic effect which assume the established reversible piezomagnetic effect? On the evidence available at present I consider that it does not.

Graham *et al.*[1] reported that remanence was in some cases changed permanently by a temporary application of stress, and Powell[2] measured the remanence which could be produced by stress applied in a moderate ambient field. This effect has been termed 'stress-aided viscous magnetization'[3] but the term 'piezoremanent magnetization', or 'PRM', conforms better to conventional terminology. It occurs because stress modifies the potential barriers which restrict the movement of domain walls, making possible magnetic changes which would not otherwise occur. In a grain of demagnetizing factor N such changes tend towards the equilibrium magnetization H/N in a small ambient field H. Thus rocks are magnetized in a field by the application of stress and demagnetized in the absence of a field.

The magnitude of the remanence which a rock acquires by applying a field without stress is a strong function of the field, being negligible in fields comparable with that of the Earth (about 0·5 œrsted) but often quite appreciable in fields of the order 80 œrsteds, as used by Nagata and Kinoshita. Observations made in fields more than 100 times as strong as that of the Earth can scarcely be used to draw conclusions about the importance of irreversible effects in seismomagnetic calculations.

Another important problem raised by Nagata and Kinoshita and also by Kern[4] is the choice of experimental data on the piezomagnetic effect. They favour the results of Grabovsky and Parkhomenko[5], but these are irrelevant to a general calculation of the seismomagnetic effect because they refer to rocks with abnormally high concentrations of magnetic minerals (80–100 per cent), whereas common rocks do not contain more than about 10 per cent by volume and most contain much less. The stress-dependence of magnetic susceptibility $\chi(\sigma)$ of a rock in the direction of stress σ is given by[6]:

$$\frac{\chi(\sigma)}{\chi(0)} = \frac{1}{1 + s\sigma}$$

where:

$$s = \frac{3/2\lambda_s}{|\frac{2}{3}(K_1 + \frac{1}{3}K_2)| + \frac{1}{2}NI_s^2},$$

λ_s, K_1, K_2 and I_s are the saturation magnetostriction, the first and second anisotropy constants and the saturation magnetization, respectively, of its magnetic mineral. N is the demagnetizing factor of the individual magnetic grains so long as they are sufficiently widely separated for grain interactions to be neglected, that is, in rocks containing only a small per cent of magnetic minerals. In rocks with higher concentrations of magnetic mineral the self-demagnetizing field within each grain, due to its own magnetic moment, is partly compensated by the magnetizing field due to the moments of the surrounding grains and this reduces the effective value of N. For grains within a pure mineral $N = 0$ (although in some experiments the demagnetizing factor of the whole specimen must then be taken into account instead). For this reason, the specimens used by Grabovsky and Parkhomenko were much more stress-sensitive than any rocks likely to be of interest in seismomagnetic work. On the other hand, Kapitsa[7] experimented with common basic igneous rocks typical of those found in many seismic and volcanic areas. His average value of s is 1×10^{-4} cm²/kg, which further work is unlikely to revise drastically; this is the figure which I have used[8,9] for approximate calculations of the seismomagnetic effect.

In so far as it is reversible, the variation of remanent magnetization with stress is similar to the variation of susceptibility as given by the above equations, but irreversible changes may be superimposed. However, in seismically active areas where the stresses have been cycled many times during recent geological history and the rocks are therefore in a cyclic state, irreversible effects of the type considered by Nagata and Kinoshita can be disregarded.

For these reasons I consider the use of Kapitsa's data on the reversible piezomagnetic effect in seismomagnetic calculations to be satisfactory. The serious doubt which does arise concerns the seismic stresses which are not at all well understood, either as regards their extent and form or variation in time. If observations of the seismomagnetic effect differ substantially from the forms predicted, as the first reports[10,11] indicate that they do,

then erroneous assumptions in the theory must be sought first in the earthquake mechanism.

PHYSICS

Apparent Anisotropy Field of Continuous Magnetic Films subjected to Inhomogeneous Drive Fields

Mr. J. G. Edwards[1] has attempted to explain the high values of anisotropy field measured under strip line conductors by equating the total anisotropy torque with the total applied field torque. He states that the total stray field torque is always zero. It is easy to show that this is, in fact, not the case. Using Mr. Edwards's notation, the stray field for $l \to \infty$ is:

$$H_s = \int_{-\infty}^{\infty} 2Mf \frac{\partial\,(\sin\theta)}{\partial x'} \frac{\mathrm{d}x'}{x' - x} \text{ in E.M.U.'s}$$

Hence the total or net torque:

$$T_s = Mfl \int_{-\infty}^{\infty} H_s \cos\theta \,\mathrm{d}x$$

The distribution of H_s and $\cos\theta$ are shown schematically in Fig. 1. As

$$\int_{-\infty}^{\infty} H_s \,\mathrm{d}x \propto \iint_{-\infty}^{\infty} \frac{\partial(\sin\theta)}{\partial x'} \frac{\mathrm{d}x'}{x' - x} \,\mathrm{d}x = \int_{-\infty}^{\infty} \frac{\partial(\sin\theta)}{\partial x'} \int_{-\infty}^{\infty} \frac{\mathrm{d}x}{x' - x} \mathrm{d}x'$$

is always zero, it is clear that $\int_{-\infty}^{\infty} H_s \cos\theta \,\mathrm{d}x$ will not be zero unless $\cos\theta$ is independent of x. This is approximately true for small values of θ and, therefore, the theory, developed by Mr. Edwards for small values of θ only, is also approximately correct. For larger values of θ, contrary to Mr. Edwards's assertion, the net torque is not zero. Consequently, his statement that, however large the applied field, the magnetization beneath the drive strip could never quite reach the hard direction, is also incorrect. There is nothing inconsistent about the distribution where the magnetization is in the hard direction under the influence of a large applied field for $|x| \ll w/2$ so that in this region the torque is zero, whereas for $|x| \geqslant w/2$ the anisotropy and stray field torques are equal. The coupling between the two regions is provided by exchange in two very narrow strips at $x = \pm w/2$. In this case, the net stray field torque, far from being zero, is equal to the net anisotropy torque.

Furthermore, Mr. Edwards's observations cannot be said to be an explanation for the anomalously high values of effective anisotropy field unless the coupling causing the observed values of p can be accounted for. As the p values observed are very much higher than those that could be due to macroscopic magnetostatic coupling alone,

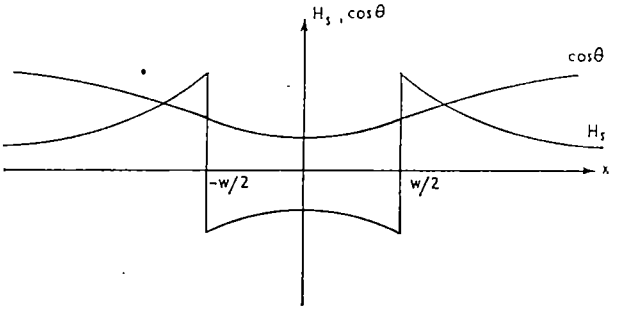

Fig. 1. The schematical distribution of H_s and $\cos\theta$ indicating that, if $\int_{-\infty}^{\infty} H_s \,\mathrm{d}x = 0$, then $\int_{-\infty}^{\infty} H_s \cos\theta \,\mathrm{d}x \neq 0$

it would be more correct to say that the anomalously high values of anisotropy field and the anomalously high values of p are corollary observations, both still awaiting explanation.

[1] *Nature*, **203**, 710 (1964).

I thank Dr. Bonyhard for his comments and agree that the net total torque caused by stray fields due to the film can never be zero. I was originally led to this erroneous conclusion in the search for a general theory independent of the nature of the coupling and by thinking that the dictum "action and reaction are equal and opposite" applied to any pair of torques as well as any pair of forces. However, the analysis of the increase in effective anisotropy field still holds: it is merely necessary to introduce the limitation that $\cos\theta \simeq \cos\theta_0 = 1$, already used to integrate equation (4), when equating equations (1) and (4). So long as changes in $\cos\theta$ are small over the range of the stray fields the balance of torques can still be used.

Whether the propagation provides an explanation of the anomalously high values of effective anisotropy field is a question of scientific philosophy. The experiments have shown that there is a strong correlation between the observed increase in anisotropy field and the propagation distance, and on the basis of a balance of torques one can be predicted from the other. At present, due to purely mathematical difficulties, we cannot be certain what values of propagation constant could be due to macroscopic magnetostatic coupling alone, but given that the propagation does occur we can 'explain' the anomalously high values of effective anisotropy field. This seems to be an advance in our understanding of the problem, albeit a small one.

Radon Content of Rainwater

In recent years, interest has been renewed in the measurement of the radon content of the atmosphere[1-4]. In most cases, samples of air were drawn through fine grain filter papers and the activity of the filter-paper samples, corresponding to radium *A*, *B* and *C*, was afterwards estimated by a suitable Geiger–Müller counter and scaling system. It was, however, found that the filter

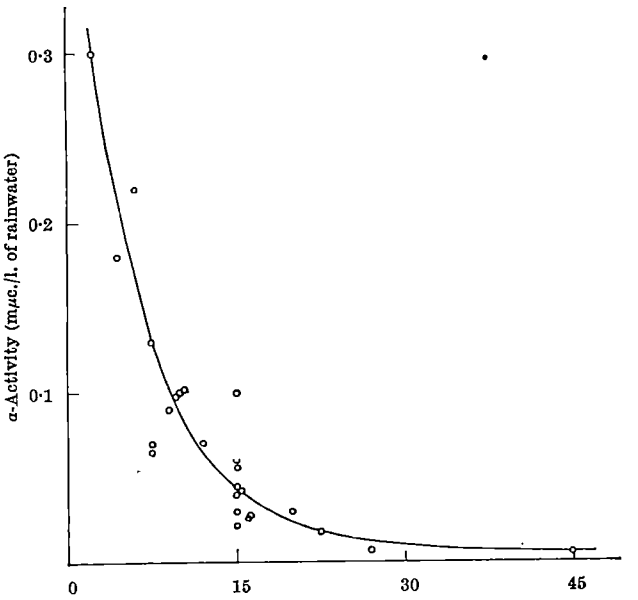

Fig. 1

paper method had a low collection efficiency of only 2–3 per cent as compared with the less equivocal ion chamber method[1]. Furthermore, Běhounek and Majerová[5] reported that there was no reason for assuming the ratio between the two measurements to be constant.

The natural radioactivity of rainwater was first reported by Wilson[6], with a half-life of about 30 min. Bumstead[7] identified the decay products captured by cloud droplets and brought to the surface by atmospheric precipitation to consist predominantly of radium $B + C$. More recently, Damon and Kuroda[8] reported that in their measurements on the natural radioactivity of rainfall the activity varied from 1 mμc. to 60 mμc./l. of rainwater and was due primarily to radium $B + C$. Since radon is present throughout the atmosphere, it continually supplies decay products which become attached to aerosols and condensation droplets. The equilibrium between radon and radium $A + B + C$ being established in about 4 h, the former should be essentially in equilibrium with the short-lived decay products in a certain volume of air, unless some disturbing force such as precipitation upsets this equilibrium. According to Damon and Kuroda[8], the decay products are swept downwards by growing raindrops, and if the rainfall is heavy, the atmospheric radioactivity will be essentially limited to the gas radon and the short-lived decay product radium A supplied directly by radon. Although the amount of radon in the atmosphere[9] is affected by meteorological conditions, it was postulated that owing to its long half-life and low concentration in rainwater a rapid depletion of radon is prevented during the course of a storm. It was therefore considered worth while to measure directly the radon content in rainwater.

During the most recent rainy season in Calcutta, the radon content of about forty separate samples of rainwater was measured. The rainwater was collected into a 2-l. flask, through a wide-mouthed glass funnel, the stem of which reached the bottom of the flask and was kept water-sealed. The separation coefficient of radon between water and air being 0·25, at 20° C, the air space in the flask retains four times as much radon as is contained in the same volume of water. Consequently, the air displaced by the collected rainwater was not allowed to escape but was trapped in a rubber balloon connected to the flask. The air laden with radon, together with the radon released by boiling rainwater, was flushed into a 3-l. evacuated ion chamber, with appropriate gas. Measurement was commenced after 3 h when the radon settled down into equilibrium with its decay products. The ion-chamber had been previously calibrated with a Hönigschmid radium substandard obtained from the Radium Institute, Vienna. The specific activity of radon varied from 5×10^{-12} c./l. to 3×10^{-10} c./l. It was noted that maximum specific activity could be associated with scant and isolated rainfalls. The specific activity rapidly diminished with the amount of rainfall as shown in Fig. 1. It was also noted that for equivalent rainfalls the specific activity of nocturnal rains was usually less than that of diurnal rains, indicating a confirmation of the diurnal variation of the radon content of the atmosphere[10].

We thank Prof. Berta Karlik and Dr. F. Hernegger of the Radium Institute, Vienna, for the gift of the radium substandard. We also thank Dr. F. Baumgärtner of the Institute of Radiochemistry, Technische Hochschule, Munich, for chemical treatment of the substandard.

GEOLOGY

A Possible Western Continuation of the Scandinavian Caledonian Arc System

In a recent communication[1] an outline is given of the primary and secondary arcs[2] in the Scandinavian Caledonian chain. I should here like to direct attention to a possible western continuation of this arc system.

Dr. M. Lindström[3] has prepared a synopsis of axial strikes (lineations and sub-vertical s-surfaces) indicated on published maps of areas in the Scandinavian Caledonides. An important feature is the prominent west-north-westerly trend of the axial records in the western part of southern Norway.

I should also like to mention the gneiss area on the coast west of Bergen. Potassium/argon determinations of micas from pegmatites in this area gave the Caledonian ages 413 (ref. 4), 425, 434 and 450 million years[5]. The gneisses can be interpreted as being the core of an anticline. The lineations (axes of minor folds and stretching) have a west-north-westerly direction[6].

In my opinion this west-north-westerly trend of the axial records in the western part of southern Norway belongs to a primary arc west of the Möre arc. This western arc is supposed to continue to Scotland, and can be named the Scotland arc (Fig. 1). In actual fact the western part of southern Norway exhibits a corresponding junction of two primary arcs, as can be studied in central and in northern Norway.

The secondary arc formed at the junction of the Scotland arc and the Möre arc consists of two parts, an uplifted massif or welt of the Precambrian basement, and, farther from the primary arcs, a basin with thrust and folded Caledonian sediments. The Precambrian basement is exposed on the south and the south-east side of the Hardanger Fjord. A potassium/argon determination of mica from pegmatite on the south side of the fjord gave the pre-Caledonian age 904 million years[5]. A possible

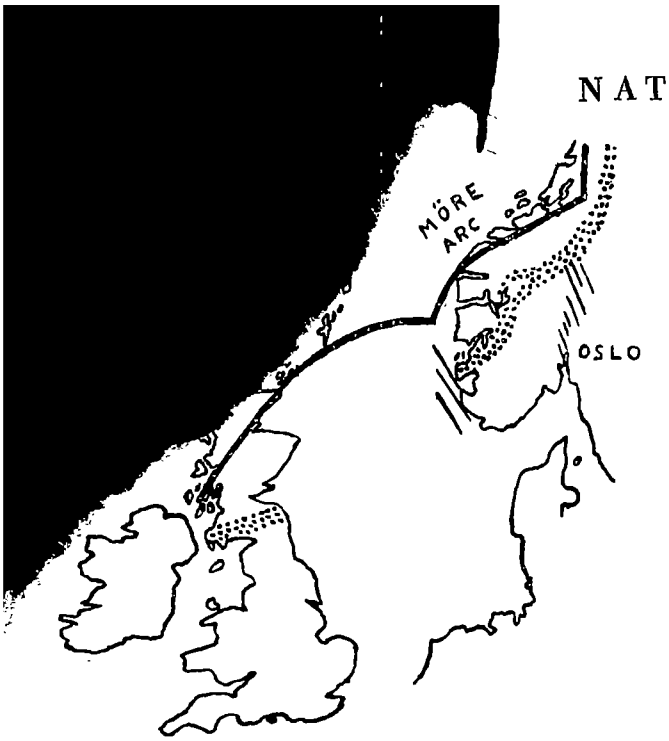

Fig. 1. Part of the British–Scandinavian Caledonian chain, an inactive narrow mountain system. Heavy lines represent axis of primary arcs, welts of secondary arcs are stippled, and graben are indicated by hatching

Caledonian origin has been discussed for this area, an interpretation which is contradicted by this figure. The Stavanger district is a preserved part of the basin.

The graben corresponding to this secondary arc is the south-western part of the Norwegian Channel.

According to Cloos[7], the origin of the Oslo region, the fault lines outside the west coast of southern Norway, and the Tertiary volcanic region of the British Isles can be explained as the result of movements between Grossblöcke of the crust of the Earth. This hypothesis seems to be in good accordance with the interpretation of the Scandinavian–British Caledonian chain as a narrow mountain system. The fault lines have repeatedly been exposed to fault movements; for example, some of the Permian fault breccias in the Oslo region are accompanied by older breccias.

RADIATION CHEMISTRY

Pulsed Radiolysis of *Cyclo*hexane Solutions: Evidence for Reactions of Electrons

Recent investigations[1] of the effect of N_2O in the γ-radiolysis of liquid *cyclo*hexane have provided strong indirect evidence for reactions involving radiation-produced electrons. The results have confirmed the suggestion of Hamill *et al.*[2] that electron attachment can occur in irradiated liquid alkanes when suitable acceptors are present.

In this communication we report the results of some experiments carried out in *cyclo*hexane solutions using the technique of pulsed radiolysis, and these results provide corroborative evidence for the foregoing hypothesis.

*Cyclo*hexane solutions, de-aerated, were irradiated with 2-MeV electrons in single 2-μsec pulses. The irradiation assembly used was essentially as previously described[3], except that the method of kinetic spectroscopy was utilized. The mean dose delivered to the solution by one pulse was approximately 8 krads.

Diphenyl was selected as one of the solutes, since the diphenylide anion has a characteristic absorption spectrum[4], and, moreover, has already been observed in the radiolysis at −196° C of alkane glasses containing diphenyl[5]. Irradiation of solutions of diphenyl (10 mM) led to the formation of a transient absorbing in the visible, having a maximum around 6500 Å. This is shown by the results given in Fig. 1. Curve (*a*) shows the absorption of the irradiated solutions measured at the maximum of the oscillograph traces almost immediately (1–2 μsec) after the pulse of electrons was delivered. Curve (*b*) indicates the corresponding absorption after a period of 40 μsec. We attribute the absorption at 6500 Å to the diphenylide anion, which is known to have a wide absorption band in this spectral region[4]. (In the experiments described here the detailed band structure of the transient spectrum could not be ascertained, owing to the rather wide band-width used in the spectroscopic determination.) The results at the lower wave-lengths of Fig. 1, where the diphenylide ion also absorbs, are apparently complicated by the presence of more than one radiation-produced intermediate.

Further confirmation that the transient is the diphenylide anion follows from investigations of the effect of N_2O. Saturation of the diphenyl-*cyclo*hexane solutions with N_2O prior to irradiation led to a decrease in the yield of the transient, as is shown by curve (*c*). This observation is interpreted in terms of a competition between N_2O (an efficient electron scavenger[6]) and diphenyl for the available radiation-produced electrons.

Some preliminary pulse experiments have also been carried out using de-aerated solutions of benzophenone (10 mM) in *cyclo*hexane. As in the case of the pulsed radiolysis of aqueous and methanolic solutions of this solute[7], two radiation-produced transients absorbing in the visible region have been observed, one having an absorption maximum around 5300 Å, the other, which is much shorter lived, exhibiting a broad absorption maximum in the region 7000–7500 Å. The yield of both these transients is decreased if N_2O is present. On the basis of this and the previous experiments[7], we attribute the absorption at 5300 Å to the presence of the free radical $(C_6H_5)_2\dot{C}$—OH, and that at the longer wave-length to the

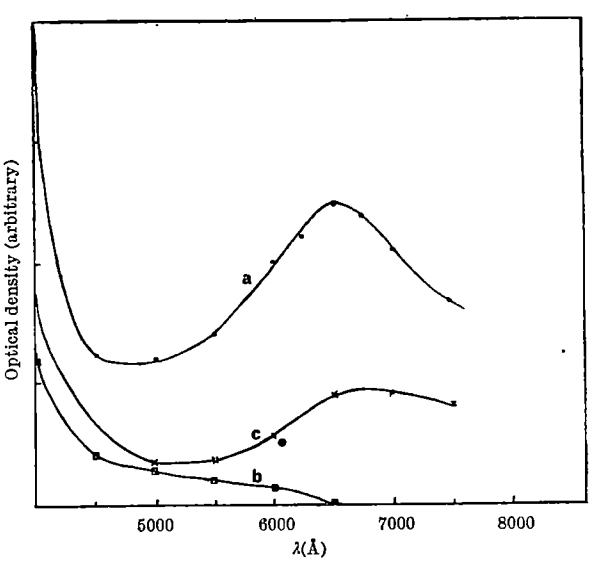

Fig. 1. Absorption spectra in solutions of diphenyl (10 mM) in *cyclo*hexane, (*a*), immediately after the pulse; (*b*), after 40 μsec; (*c*), in the presence of added N_2O (~50 mM), immediately after the pulse

presence of the radical-ion $(C_6H_5)_2\dot{C}—O^-$. (The radical ion absorbs at a somewhat higher wave-length in *cyclo*hexane than in the foregoing more polar liquids.)

Since these experiments indicate radical anion formation in irradiated alkane solutions, thereby substantiating the conclusions derived from chemical investigations, reactions of electrons should be taken into account in any interpretation of the radiation-induced decomposition of hydrocarbon systems.

CHEMISTRY

Transport Processes in Low-melting Fused Salts

The experimental results of measurements of the viscosity and electrical conductance of molten salts have been expressed by many authors in the forms:

$$\eta = A_\eta e^{E_\eta/RT} \text{ and } \Lambda = A_\Lambda e^{-E_\Lambda/RT}$$

in which E_η and E_Λ are known as the activation energies for viscous flow and for equivalent conductance, respectively. The data frequently can be fitted with reasonable accuracy to equations of this type in which the pre-exponential factors (A_η, A_Λ) and the activation energies are independent of temperature in the temperature-range of the measurements, although there are exceptions.

It was observed by Heymann and Bloom[1] that for molten alkali halides, E_Λ is always greater than $E_\varkappa$, the activation energy for specific conductance. It has been demonstrated by Martin[2] that the latter is rather less than E_Λ, the difference being given by:

$$E_\Lambda - E_\varkappa = \alpha RT^2$$

in which α is the expansivity of the melt. Nevertheless, the ratio E_η/E_Λ, denoted by m, is found to lie between about 2 and 5 for the alkali halides when use is made of the best data at present available for the viscosities and equivalent conductances. The fact that E_η is considerably greater than E_Λ has been explained in terms of the configurational changes involved in the two transport processes. It is generally accepted that the molten alkali halides can be regarded as being completely dissociated into positive and negative ions[3]. Viscous flow presumably necessitates equal participation by the two types of ion, and hence is governed primarily by the larger species, while electrical conductance is associated predominantly with the motion of the smaller species, that is, the cations in the case of the alkali halides. It is of interest to apply these concepts to the transport properties of ionic melts in which the ions do not possess spherical symmetry. The quaternary ammonium salts are a convenient group in this category.

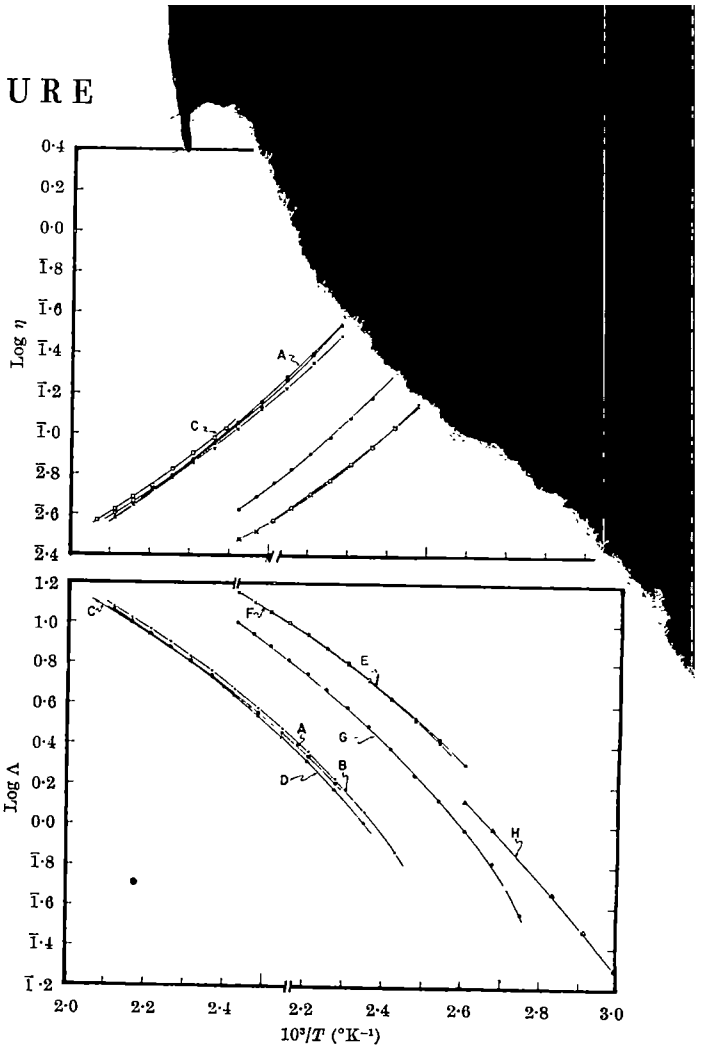

Fig. 1

Compared with most other ionic solids, the quaternary ammonium salts possess low melting points, generally in the range 50°–200° C. This fact may be connected with the relatively large separation of oppositely charged centres in the crystalline state, and with the dispersion of the total unit charge over a polyatomic species such as $\overset{+}{N}R_4$ or SCN^-. On account of the lower temperature range involved, the quaternary ammonium salts are more readily handled than most ionic melts, permitting greater accuracy in measurements of such properties as density, viscosity and conductance.

Results of the equivalent conductance and viscosity for seven tetraalkylammonium picrates have been given by Walden, Ulich and Birr[4], and for tetra-*n*-amylammonium thiocyanate by Kenausis, Evers and Kraus[5]. The graphs of log η and log Λ against $1/T$, shown in Fig. 1, are smooth curves; both E_η and E_Λ decrease with increasing temperature for each salt. The high precision of the data enables the temperature dependence of E_η and E_Λ, and of the ratio $E_\eta/E_\Lambda = m$, to be examined closely. Values of these quantities at a number of temperatures for the eight salts are given in Table 1.

Table 1. E_η AND E_Λ FOR QUATERNARY AMMONIUM SALTS

Salt	m.p. (° C)	Temperature (° C) 110° E_η	110° E_Λ	150° E_η	150° E_Λ	190° E_η	190° E_Λ
Me_3Pr_1NPic	93·0	$8·9_5$	$8·2_0$	$7·4_0$	$6·7_5$	$6·0_0$	$5·6_5$
Et_3Pr_1NPic	79·9	$8·6_0$	$8·4_5$	$6·9_0$	$6·5_5$	$6·0_0$	$5·5_5$
$Et_3PrNPic$	144·2	—	—	$7·1_5$	$6·7_5$	$6·0_5$	$5·5_5$

$EtPr_3NPic$	107·2	$9·1_0$	$8·9_0$	$7·2_5$	$6·8_0$	$6·3_5$	$5·8_0$
Pr_4NPic	119·6	—	—	$7·5_5$	$6·9_5$	$6·3_0$	$5·7_0$
$(n\text{Am-})_4NSCN$	50·5	$9·5_5$	$8·7_5$	—	—	—	—
$(i\text{Am-})_4NPic$	87·0	$10·9_0$	$10·3_5$	$8·7_0$	$8·1_5$	$7·2_0$	$6·6_5$

Me, methyl; Et, ethyl; Pr, propyl; *n*Am, *n*-amyl; *i*Am, iso-amyl Pic, picrate.

For $(n\text{-amyl})_4$NSCN (m.p. 50·5° C) the E_η and E_Λ values at 60° are $11{\cdot}6_0$, $11{\cdot}4_5$ kcal/mole respectively, and at 90°, $10{\cdot}0_0$, $9{\cdot}4_0$ kcal/mole respectively.

The following points are noted: (1) E_η is always greater than E_Λ, but the values are similar, m falling between 1·0 and 1·1; values of m vary only slightly with increasing temperature, showing a small increase in most cases. (2) E_η and E_Λ at any given temperature show little dependence on the constitution of the cation when the alkyl groups are methyl, ethyl or propyl; slightly higher values are observed when R = n-amyl or iso-amyl.

It is inferred from the similarity between E_η and E_Λ that there is a close resemblance between the configurational changes involved in viscous flow and in conductance in these salts. It appears, therefore, that electrical conductance here requires in a high degree the co-operative movement of both anion and cation. Two possible reasons for this can be envisaged: (1) the existence in the melt (for times which are long compared with those involved in the relaxation of the applied electrical or mechanical stresses) of some form of ion association, which has been suggested by Davis, Rogers and Ubbelohde[6] as occurring in the nitrates of the alkali metals and of silver; (2) steric factors associated with the size, shape and relative orientation of the ions in the melt, such that neither species may be regarded as being kinetically 'free', in contrast to the small spherical alkali-metal ions in melts of the alkali halides.

In connexion with the question of association in quaternary ammonium salts, Walden *et al.*[7] suggested that these salts were completely dissociated in the liquid state. (It should be noted that interionic interactions of the type leading to partial covalency formation are precluded in the case of quaternary ammonium salts.) An important piece of evidence put forward by Walden *et al.* concerned the magnitude of the quantity $\eta\Lambda$ (the Walden product). The value of $\eta\Lambda$ for the molten picrates was found to be similar to that for infinitely dilute solutions of these salts in water and several other solvents, in which complete dissociation is assumed. Furthermore, optical investigations of the picrate ion indicated that the quaternary ammonium picrates behaved like typical strong electrolytes.

We therefore prefer to explain the observed similarity of E_η and E_Λ in these salts in terms of steric factors rather than in terms of ion-aggregate formation. The particular case of tetra-n-amylammonium thiocyanate has been examined in some detail. From the density data[5] it is clear that the average volume available to a 'molecule' of this salt in the liquid at 52° C is 656 Å^3. The $\overset{+}{N}(n\text{-amyl})_4$ group, with the four alkyl chains tetrahedrally disposed about the nitrogen atom, requires for 'free rotation' in the melt a volume of more than 1000 Å^3. Attempts to construct a model of the salt consistent with observed bond distances and with the density of the liquid show clearly that the $\overset{+}{N}(n\text{-amyl})_4$ groups must be relatively closely packed, in such a way that there is considerable interference between the alkyl groups of one ion and those of adjacent ions. This situation is shown schematically in Fig. 2. Such a closely packed assemblage of $\overset{+}{N}R_4$ ions does, however, possess interstices of sufficient size to accommodate the SCN^- ions, with length about 4·6 Å and radius 0·7–1·1 Å. According to this, free rotation of $\overset{+}{N}R_4$ ions is not possible at the temperatures involved here, and migration of SCN^- ions from one interstitial position to another is subject to considerable hindrance. This is borne out by the large activation energy for conductance, 11·6–8·75 kcal/mole between 52 and 110° C, compared with values of 2–4 kcal/mole for most molten salts with spherical ions. The reasons for the high viscosity (27–323 cP. in the range 52°–110° C) and the similarity of E_η and E_Λ are also apparent, as unit transport processes are considered to occur by means of a large number of co-operative rotational-vibrational movements of ions of opposite charge. The small increase in m with temperature generally observed in quaternary ammonium salts is explained in terms of greater freedom for the movement of the smaller ion at higher temperatures.

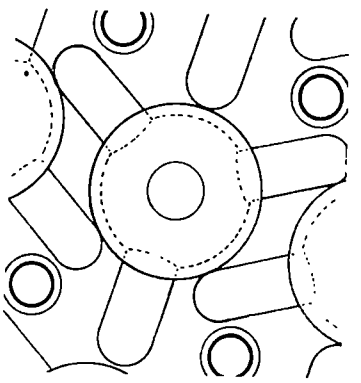

Fig. 2

In the case of the picrates, even when the alkyl chains have less than five carbon atoms, added interference and restriction on single-ion movement is provided by the nitro-groups of the picrate ion. It is concluded that gegen-ion co-operation in both transport processes for single salt melts does not necessarily indicate the presence of associated ionic species, but may arise in a fundamental way from the steric requirements of the ions and the available free space in the liquid.

Information on the crystal structure of the solid salts and on details of the fusion parameters such as $\left(\frac{\Delta V_f}{V \text{ solid}}\right)$ should prove interesting in the light of the comparative closeness of packing required in the liquid.

Metal Ion Catalysis in the Hydrolysis of Potassium Ethyl Oxalate

Hoppé and Prue[1], during an investigation of kinetic salt effects in the hydrolysis of the half esters of dicarboxylic acids, found that calcium(II), barium(II) and hexammino cobalt(III) ions had a slight catalytic effect on the hydrolysis of potassium ethyl oxalate. The reaction was examined using equimolar quantities of sodium hydroxide and ester (0·01 M) in the presence of the various metal salts, conditions unsuitable for investigations of the effect of transition metal ions on the reaction. We wish to report catalysis by copper(II) and nickel(II) ions in this reaction.

The pH of solutions of potassium ethyl oxalate (0·005 M) decrease quite rapidly with time on addition of copper(II) or nickel(II) ions (0·011 M); but there is no observable effect with barium(II) ions, at this concentration.

The pH of the solution will decrease if hydrolysis occurs, as attack by a water molecule on the ester leads to the liberation of a proton:

The hydrolysis was followed by means of automatic titrator ('Radiometer TTT-1') as a *p*H-stat to monitor generation of acid in the solution. The reaction was found to obey first-order kinetics when the *p*H was held constant and the pseudo-first-order rate constants were obtained from data on the first 50 per cent reaction. In a number of runs the rate decreased after approximately 50 per cent reaction. At the metal ion concentrations used, the predominant complex in solution is $MEtOx^+$; the decrease in rate could be due to the initial formation of two different complexes such as $MEtOx^+$ and MEtOx(OH), which hydrolyse at different rates, or to the formation of a complex between the metal ion and the product such as MOx, which is more stable than $MEtOx^+$. That this second effect does, in fact, occur is supported by a number of observations. A kinetic run was attempted at *p*H 5·5 with 0·005 M potassium ethyl oxalate and 0·005 M copper(II) in the presence of 0·05 M potassium oxalate; during 60 min no hydrolysis was detected. A second run at *p*H 5·5 using *bis*(ethylene diamine) copper(II) perchlorate as catalyst also showed no hydrolysis. Presumably in this case $EtOx^-$ cannot compete with ethylene diamine for the metal ion.

The observed first-order rate constants for the copper(II) and nickel(II) catalysed hydrolysis carried out with an ester concentration of 0·005 M in 0·300 M potassium nitrate are listed in Table 1.

Table 1. Rate Constants for the Copper(II)- and Nickel(II)-catalysed Hydrolysis of Potassium Ethyl Oxalate at 25·06° C

Metal ion	[M(II)]	*p*H	$10^3 k_{obs}$ (min^{-1})
Cu(II)	0·005	5·0	0·445
Cu(II)	0·010	5·0	0·99
Cu(II)	0·015	5·0	1·54
Cu(II)	0·020	5·0	2·85
Cu(II)	0·005	5·5	1·10
Ni(II)	0·005	7·8	1·27
Ni(II)	0·010	7·8	2·60
Ni(II)	0·015	7·8	6·0

The reaction was also examined at a number of ionic strengths at *p*H 5·5 with a copper(II) concentration of 0·005 M. The following rate constants were obtained: $k_{obs} = 1{\cdot}08 \times 10^{-2}$ min^{-1} ($I = 0{\cdot}15$), $k_{obs} = 1{\cdot}08 \times 10^{-2}$ min^{-1} ($I = 0{\cdot}30$) and $k_{obs} = 1{\cdot}05 \times 10^{-2}$ min^{-1} ($I = 0{\cdot}45$). The rate of hydrolysis is, therefore, independent of ionic strength at *p*H 5·5, indicating that hydrolysis probably occurs by reaction of the complex with a water molecule rather than a hydroxide ion.

Measurements were made at three temperatures at *p*H 5·5 and a copper(II) concentration of 0·005 M, $k_{obs} = 1{\cdot}10 \times 10^{-2}$ min^{-1} (25·06°), $k_{obs} = 1{\cdot}84 \times 10^{-2}$ min^{-1} (30°), and $k_{obs} = 3{\cdot}50 \times 10^{-2}$ min^{-1} (37°), from which $\Delta H^+ = 17{\cdot}10$ kcal. mole^{-1} and $\Delta S^+ = -18{\cdot}3$ e.u.

Attempts were made to detect hydrolysis of potassium ethyl malonate and potassium ethyl succinate in the presence of copper(II) ions at *p*H 5·5 and with nickel(II) ions at *p*H 7·8. No hydrolysis was observed at 25·06° and at 30° but very slow hydrolysis appeared to occur at 37°. The greater effect with oxalate is in line with the expected greater stability of the oxalate complexes.

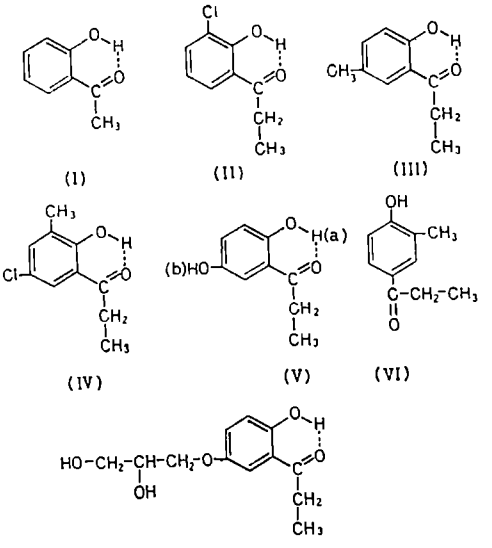
Proton Magnetic Resonance of the Hydrogen Bond in Phenols



It is well known that the hydrogen bond gives rise in phenols to a large shift of the hydroxyl proton[1–6]. In a variety of compounds in which the OH groups are intermolecularly bonded, several workers have examined the chemical shifts of the hydroxyl proton in both the monomeric and polymeric compound, through the signal frequency variation which follows dilution in solvents.

A halogen atom *ortho* to the phenol OH forms an intramolecular hydrogen bond of medium strength with the hydroxyl group, giving rise to a remarkable low-field shift of the OH signal, while *ortho* substituents, containing a carbonyl or nitro group, give rise to considerably larger paramagnetic shifts, which are substantially independent of the concentration.

The phenols in which the internal hydrogen bond is formed by the OH with the donor oxygen atom of a carbonyl group are of particular interest. Batdorf[1] and, later, other workers[3,4] have examined salicylaldehyde and some salicylates in CCl_4 solution, with reference to *cyclo*hexane as an internal standard: the OH signal occurs at 9·53 and 9·13 p.p.m., respectively, for salicylaldehyde and methyl salicylate. Among the *ortho*-acylphenols, *o*-acetylphenol (I) only has been measured[4], which showed a chemical shift of 10·63 p.p.m. in CCl_4 solution and with reference to *cyclo*hexane.

It is the purpose of this communication to discuss the proton resonance of the OH group in acylphenols, and to compare the shifts found for these compounds with those of other bonded phenols.

The following compounds have been considered in my work: 2-acetylphenol (I), 2-propionyl-6-chlorophenol (II), 2-propionyl-4-methylphenol (III), 2-propionyl-4-chloro-6-methylphenol (IV), 2-propionyl-4-hydroxyphenol (V), 2-methyl-4-propionylphenol (VI), and 2-propionyl-4-hydroxyphenol α-glycerol ether (VII). While (I), (II), (III) and (IV) were measured in CCl_4 solution, the less-soluble (V), (VI) and (VII) were measured in $CDCl_3$. Tetramethylsilane (TMS) was used in each case as an internal standard. Measurements were made on a Varian *A*-60 spectrometer in a radio-frequency range of 0·15–0·25 milligauss.

Chelate acylphenols exhibit large paramagnetic shifts of the hydroxyl proton: 12·07 p.p.m. for (I) (at a 0·67 M concentration), 12·68 p.p.m. for (II) (at 0·33 M), 11·93 p.p.m. for (III) (at 0·56 M), 12·40 p.p.m. for (IV) (at 0·44 M), and 12·02 p.p.m. for (V) (at 0·36 M). These frequencies are substantially independent of the concen-

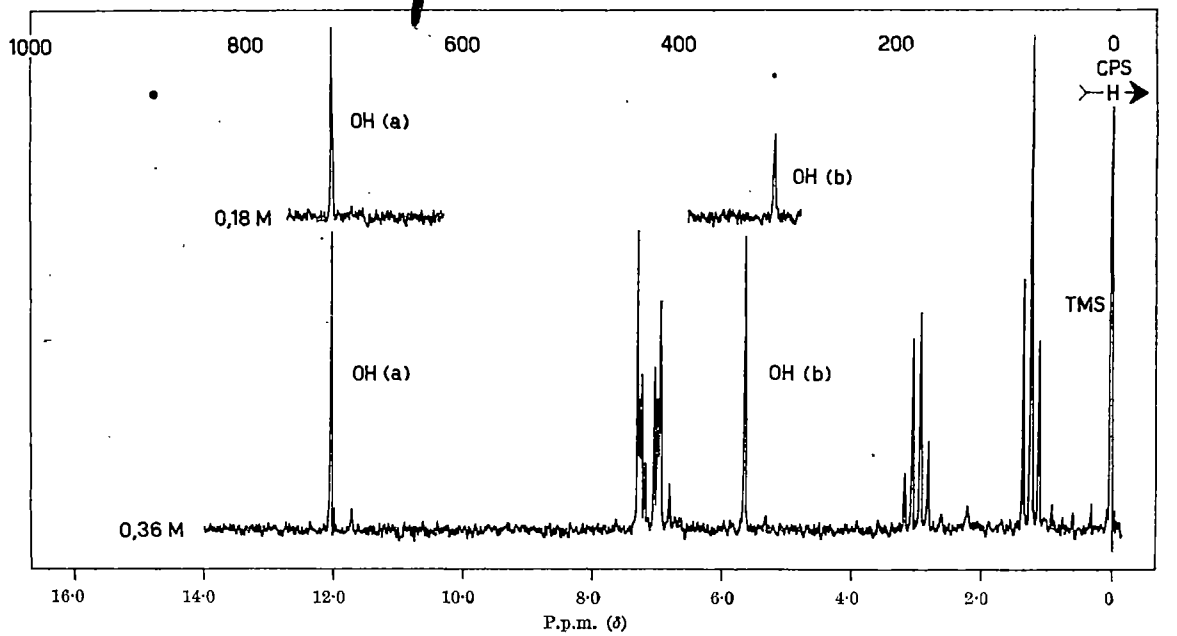


Fig. 1. Proton magnetic resonance spectrum of 2-propionyl-4-hydroxyphenol (V)

tration: the signal of (V), for example, shifts to 11·93 p.p.m. only at a 0·18 M concentration. The value found for 2-acetylphenol (I) is in close agreement with that found by Porte *et al.*[4], if their value is, of course, related to tetramethylsilane rather than to *cyclo*hexane. The frequencies are not remarkably affected by the solvent nature: the values found in CCl_4 show a difference of a few c.p.s. only from those measured in $CDCl_3$.

2-Propionyl-4-hydroxyphenol (V) is of considerable interest, and its spectrum is shown in Fig. 1. In fact, other than the signal at 12·02 p.p.m., it exhibits another signal at 5·63 p.p.m., owing to the hydroxyl (*b*) which is *meta* to the propionyl group. The difference in chemical shift between the two OH is clearly to be attributed to the fact that, while OH (*a*) is capable of giving an intramolecular hydrogen bond with the carbonyl–oxygen atom, OH (*b*) can give an intermolecular bond only. The signal of the OH (*b*) proton, therefore, shifts to 5·10 p.p.m. and tends to broaden on dilution (at a 0·18-M concentration), while the other signal shifts of a few c.p.s. only and remains sharp. Accordingly, the two hydroxyl groups show a different reactivity: by reacting the monosodium salt of (V) with glycerol α-chlorohydrin, (VII) is obtained, which exhibits the phenol OH signal at 12·00 p.p.m. at a 0·23 M concentration. The ether bond has thus been formed on the OH (*b*), and the fact that the chelate hydroxyl signal occurs at the same frequency as in (V) is evidence that this type of intramolecular bond is little affected.

(VI), in which the OH is *para* to the propionyl group, exhibits a sharp signal at 8·87 p.p.m., at a 4·20 M concentration. This signal shifts to a higher field on dilution, and becomes correspondingly broader and broader: at a 1 M concentration, it occurs at 7·93 p.p.m. and it is very broad. These data mean that the intermolecular hydrogen bond formed by the hydroxyl group in (VI) is stronger than the normal bond formed between phenol molecules: in fact, the δ_1 of the OH protons in intermolecularly bonded, non-hindered phenols are about 7 p.p.m. in CCl_4 with reference to tetramethylsilane. This may lead to the conclusion that the hydrogen bond in (VI) is formed by the hydroxyl group with the carbonyl-oxygen atom of another molecule and, taking into account that (VI) has been examined in $CDCl_3$ (which favours the relative concentration of the more polar monomer), one would think that such a bond is very strong.

Accordingly, one may consider it very likely that the intermolecular hydrogen bond formed by OH (*b*) in (V) is not of the same type as in (VI), but rather of the type of hydroxyl–hydroxyl bond normally occurring in phenols. In (V), OH (*b*) cannot form a hydrogen bond with the carbonyl group of another molecule, since the donor oxygen atom of this group is engaged in the internal bond with OH (*a*).

I have now measured the chemical shifts of the OH protons in other phenols in which an intramolecular hydrogen bond exists between the OH and a carbonyl group present in an *ortho* substituent. The results substantially support the findings of other workers[1,3,4]: the values measured in CCl_4 were 10·98, 10·84, 11·00 and 10·58 p.p.m., respectively, for salicylaldehyde, 5-bromosalicylaldehyde, 4-iso-propylsalicylaldehyde, and methyl salicylate.

It may be concluded from this work that chelate acylphenols exhibit the signal of the hydroxyl proton at 12–12·5 p.p.m., and this is substantially independent of the concentration and of the solvent. A comparison with similar chelate hydroxyl-bodies, such as salicylaldehydes and salicylates, in which the OH proton has a chemical shift of 10·5–11 p.p.m., reveals that the intramolecular hydrogen bond occurring in *ortho*-acylphenols is much stronger. When the carbonyl-bearing substituent is not *ortho* to the phenol hydroxyl group, the OH forms an intermolecular hydrogen bond with the carbonyl–oxygen atom of another molecule, being this bond stronger than the hydroxyl–hydroxyl bond normally occurring in phenols.

I thank Dr. E. Crescenzi for supplying the compounds used in this work.

BIOPHYSICS

Differences observed between Electron Spin Resonance Signals from Surviving Tumour Tissues and from their Corresponding Normal Tissues

Commoner and Ternberg[1,2] have reported the presence of electron spin resonance signals from samples of normal rat, mouse, guinea-pig and human tissues. The samples were all surviving tissues measured quickly after the death of the animal and the signals remained for up to 100 min after death, disappearing more rapidly at the higher temperature at which the sample was maintained in the electron spin resonance spectrometer. The signals all occurred around $g = 2{\cdot}004$, indicating that free electron spins were present, perhaps in the form of free radicals, which were the origin of the resonant absorption signals. The size of signal was reasonably consistent for a given material but differed from tissue to tissue, and in the rat, mouse and guinea-pig were greatest for liver, with smaller signals from kidney and heart. Signals were also observed for intestines, adrenals and lung, but only low-intensity signals, if any, were reported for skeletal muscle and spleen.

Since then, Cook and Mallard[3] have shown a signal from normal surviving rat liver and Becker[4] has shown spectra obtained from amphibian and human whole cortical bone.

It seemed to us that one very interesting feature of Commoner's work was the observation that mouse and rat hepatoma gave scarcely any signal compared with the normal liver and we have examined a series of animal tumours and compared their signals with those from the corresponding normal tissue.

An X-band reflexion-type spectrometer developed during this project from the earlier one[3] (with a sensitivity of 10^{-6} M of Mn^{++}) was used. Small thin slices of tumour tissue (about 100 mg), which had been grafted and grown subcutaneously in otherwise healthy rats, were measured. The tumour was removed from the rat immediately after death and cut into slices, one sample being placed immediately in the spectrometer. Other samples for later use were kept in a saline solution below the freezing point. At the same time as the tumour was removed, normal tissue was removed from the same animal, the organ chosen being that type within which the tumour had originally been generated. This normal tissue was stored for later measurement.

The storage time for any tissue sample was in most cases less than a few hours and was never in excess of 1 day. Experiments were performed to confirm that this storage process did not give rise to any deterioration in the signal size measured for tissues from which signals could be obtained. Within the cavity of the spectrometer, however,

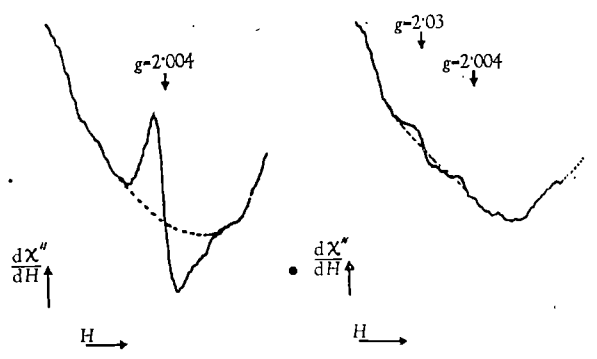

Fig. 1. Left, electron spin resonance spectrum from normal liver; right, electron spin resonance spectrum from liver carcinoma induced by butter yellow

Table 1

No. of rats from which tumours were measured	Tissue sample	Estimated concentration of spins (M)
2	Spontaneous carcinoma of renal collecting tubules	$\leqslant 10^{-6}$
	Normal kidney	$2\text{–}3 \times 10^{-4}$
2	Butter-yellow-induced carcinoma of liver	$\leqslant 10^{-6}$
	Normal liver	$5\text{–}6 \times 10^{-6}$
2	Methylcholanthrene-induced sarcoma	$\leqslant 10^{-6}$
	No normal tissue	—
2	Radiation-induced fibrosarcoma	$\leqslant 10^{-6}$
	No normal tissue	—

which is usually at about 30° C, the signals from normal liver were seen to decay slowly with a half period of about 30 min. This appears to be somewhat faster than that found by Commoner[1] in this temperature region, but he used a substrate of glucose.

The tumours used were all supplied by Dr. R. H. Thomlinson and, whatever their organ of origin, were transplanted subcutaneously through many generations. They included spontaneous, chemically-induced and radiation-induced tumours. Unfortunately no tumours were available which were growing within their organ of origin.

Table 1 shows the results on four different tumour types compared, where possible, with the nearest normal tissue. In all cases five samples were measured from each tumour. In the case of the tumours examined no definite observable signal could be detected greater than 10^{-6} M, which is our lowest limit of detection.

Table 1 also shows the number of spins observed in the signals from the normal tissue taken from the tumour-bearing rats. These agree well with those of Commoner[1]. Signals equal to these values, within a standard deviation of 30 per cent for liver and 45 per cent for kidney, have been obtained on a considerable number of samples of these tissues measured over many months before this tumour investigation was performed.

Fig. 1 shows the signals observed in the case of the rat liver carcinoma originally induced by butter yellow, and normal rat liver; the difference in size between the signals is clearly observed.

The very large background signal, on which the signals at $g = 2{\cdot}004$ are superimposed, arises from impurities in the quartz glass which is used for the sample cell; cells of pure silica will be used in future. It is possible that the same glass impurities may give rise to the small signals seen in the tumour samples at $g = 2{\cdot}004$; however, these signals may arise from the tumour itself.

A series of experiments is planned to confirm and explore these initial observations on four tumour types which show a striking difference between some malignant and normal tissues.

We thank Dr. R. H. Thomlinson of the Medical Research Council Experimental Radiopathology Research Unit at Hammersmith Hospital for the supply of tumours, and the Department of Scientific and Industrial Research for the research grant which has made this work possible.

BIOCHEMISTRY

A Comparison of Free and Bound Amino-acids from Three Tissues of *Cancer antennarius*

THE relationship of free to bound amino-acids as well as their distribution in the various types of tissues is poorly understood in invertebrates. The variation in amino-acid content of mosquitoes was shown by Mick and Ellis[1] to correlate with species differences. Recent investigations of other invertebrates have shown that environmental differences will produce a change in amino-acid composition within the same species[2]. If amino-acid composition is to be used as a measure of species relationship or as a criterion of metabolic activity a better understanding of the relationship of free to bound amino-acids and of the variability of amino-acid content from one tissue to another within an animal would be desirable. The work recorded here was carried out with this purpose in mind.

A specimen of *Cancer antennarius* was collected in a trap in the Los Angeles Harbor area, returned to the laboratory alive, and quick-frozen. The tissues to be tested were removed from the animal and immediately lyophilized without intermittent thawing. Muscle tissue, digestive gland and excretory gland were selected for analysis. Muscle was chosen because it was believed that in this tissue a fairly stable equilibrium would be represented; digestive gland was used because this represented the most active metabolic area; excretory gland tissue was included for comparison as it represented a third and different metabolic phase.

Extracts of the free amino-acids present in these tissues were made after lyophilization by permitting the dried and powdered tissue to stand in two consecutive 50-ml. aliquot portions of 70 per cent cold ethanol, in excess of 12 h each. Dry weight quantities of tissues used were 0·7343 g of excretory gland, 0·2355 g of digestive gland and 2·2609 g of muscle. Hydrolysates were prepared by hydrolysing similar quantities of these tissues in 6 N hydrochloric acid for 30–36 h.

Chromatographic analysis was carried out on 18 in. × 22 in. Whatman No. 1 filter paper. Butanol, acetic acid and water (4 : 1 : 5) was used for the first direction while water-saturated phenol was used for the second. Development was brought about by dipping in a 0·2 per cent acetone solution of ninhydrin and drying in an oven at 37°. Various concentrations of extract were chromatographed to ensure the best possible identification. Although no exact quantitative measurements were made, visual comparisons, based on spot size and intensity, were noted. In Table 1 the figures 4, 3, 2 and 1 have been used to designate these relative concentrations with 4 representing the highest and 1 the least.

The chromatographic patterns obtained from the muscle tissue of one of the chelipeds showed the following free amino-acids to be present : alanine and glutamic acid in high concentrations; serine, glycine, valine, phenylalanine and leucines in slightly lighter concentrations; threonine, proline, hydroxyproline, aspartic acid, lysine, histidine and arginine in still lighter concentrations. A faint spot in the position of tyrosine indicated its presence in small quantity.

The bound amino-acids of the muscle tissue differed from the free amino-acids of this tissue both qualitatively and quantitatively. In addition to the amino-acids already mentioned, which of necessity were present because those in free form were not removed before hydrolysis, cystine, asparagine and/or taurine (in the solvent systems used, these latter two move to the same position), and three unidentified ninhydrin-sensitive spots occurred. The leucines, alanine, proline and hydroxyproline were noticeably heavier in relative concentration. Only in the chromatograms of muscle tissue were two distinct spots detectable for proline and hydroxyproline. Because these occur very closely together in the solvent systems used in this work, they will hereafter be reported as proline, which does not exclude the possibility of hydroxyproline at the same location.

Table 1. AMINO-ACID CONTENT OF THREE TISSUES OF *Cancer antennarius*

Amino-acid	Muscle (free)	Muscle (bound)	Digestive gl. (free)	Digestive gl. (bound)	Excretory gl. (free)	Excretory gl. (bound)
Alanine	4	4	3	3	4	4
Glycine	3	3	3	2	3	3
Glutamic	4	4	4	4	4	4
Serine	3	3	2	2	3	3
Aspartic	2	3	1	4	2	2
Threonine	2	3	1	2	2	2
Lysine	2	2	1	2	3	3
Histidine	2	2	2	2	3	3
Arginine	2	2	1	2	3	3
Valine	3	4	1	3	2	1
Phenyl-alanine	3	4	1	1	2	1
Leucine	3	4	3	3	4	3
Cystine	—	1	1	1	—	
Proline/ hydroxy-proline	2	4	2	1		
Tyrosine	1	2	1	1	2	2
Methio-nine	—	—		1	—	
Aspara-gine/tau-rine	—	2	—	—	—	
Unknowns	—	1,1,1	—	—	1,1	1,1

An analysis of the free and bound amino-acids of the excretory gland showed the same amino-acids to be present in both. In each form alanine and glutamic acid appeared in heavy concentration. In the free amino-acids of the excretory gland the proportion of leucine to the other amino-acids was higher than in the bound form in this tissue. Glycine, serine, lysine, histidine and arginine occurred in both forms in slightly lighter concentrations. Aspartic acid, threonine, tyrosine, glycine and an unidentified spot occurring near glutamic acid were present in even lesser amounts. In the free form, the amounts of valine and phenylalanine were slightly greater than from the combined form.

A comparison of the free and bound amino-acids of the digestive gland showed them to be qualitatively the same. Alanine, glycine, serine, valine, phenylalanine, the leucines, proline, tyrosine, cystine and a trace of methionine occurred in both cases. Differences occurred, however, in the relative concentrations (Table 1). The most notable of these differences was seen in the case of aspartic acid. In the hydrolysate the spot produced by this acid was very heavy whereas in the free form it appeared as only slightly more than a trace.

A comparison of the analyses of the three types of tissues showed that twelve amino-acids were held in common in both free and bound forms. These were alanine, glycine, glutamic acid, serine, aspartic acid, threonine, lysine, histidine, arginine, valine, phenylalanine, leucines and tyrosine. Asparagine/taurine occurred only in muscle hydrolysate, indicating that of the tissues tested in this animal this amino-acid is a component only of muscle tissue protein. Apparently no reserve quantity, or a quantity so small as not to be detectable, occurs in the tissue fluid of the muscle in free form. This seems also to be the case for cystine in muscle. The occurrence of this amino-acid, however, is not confined solely to muscle tissue but was found also in both forms of the digestive gland analysis. In the latter case it cannot be said with certainty whether the cystine detectable occurred only in free form or in the bound form as well.

Proline was detectable in both digestive gland analyses and muscle analyses. In the case of the muscle tissue the spot formed by this amino-acid from the hydrolysate was approximately twice the relative concentration as that of the free amino-acids of this tissue, indicating that proline occurs in both forms in muscle. In the digestive gland analyses no such sharp distinctions of concentrations of this amino-acid were seen between the two forms so that although it can definitely be said to be present in free form, it cannot be said with certainty to exist in bound form. No trace of this amino-acid was noted in the

excretory gland tissue, indicating that, if it is present, the quantity is extremely minute and thus not detectable by the method used. This situation differs from that of mammalian tissue where it has been shown by Scriver *et al.*[3] that renal tubules exhibit a reabsorption preference for proline and hydroxyproline over glycine, which would suggest their presence in free form in that tissue. Their absence here is emphasized by the fact that the quantity of excretory gland tissue used for analysis was approximately three times that of digestive gland, yet this amino-acid readily seen in the latter tissue was not observable in the excretory tissue. Thus, this amino-acid would seem to be absent from the protein comprising the excretory gland, from the tissue in free form and from the filtration products present in the gland at the time of free amino-acid extraction and of hydrolysis.

Methionine was found only in digestive gland tissue in a quantity so small that the spot formed by it in both the free and combined form was barely detectable. Its existence in a minute quantity here and its absence from the other tissues analysed would suggest that it may be rapidly used as a methyl donor at this site. A correlation may exist between the presence of cystine in the digestive gland and the presence of methionine, since the latter on demethylation becomes homocystine and this through a series of reactions can participate in the synthesis of cystine[4].

This investigation was part of the work supported by research grant *WP*-260 from the U.S. National Institutes of Health.

Influence of Amino-acid Levels on Protein Synthesis *in vitro*

Although protein synthesis is obviously dependent on availability of amino-acids[1], the relationship of alterations in intracellular levels of amino-acids to rates of protein synthesis and breakdown remains obscure. Thus, enhanced protein synthesis has been observed in the presence of normal[2] as well as elevated[3] cellular levels of amino-acids. A maximum effective cellular concentration may exist for each amino-acid beyond which net protein synthesis cannot be further stimulated[4,5]. However, above this concentration alterations in gross protein synthesis may occur which are masked by concomitant variations in protein breakdown. The investigations recorded here were designed to investigate this possibility. The data indicate that a primary increase in extracellular concentration of one essential amino-acid may result in stimulation of protein synthesis and protein breakdown in surviving liver cells.

Hepatic tissue was obtained from adult male rats (160–170 g) of an inbred Sprague–Dawley strain. The animals were killed in the post-absorptive state by bleeding from the dorsal aorta under light 'Nembutal' (sodium pentobarbital) anæsthesia[6]. Slices obtained with the Stadie–Riggs slicer were 0·5 mm thick and weighed 100 mg each. Approximately 500 mg of liver slices were incubated in Krebs–Ringer bicarbonate buffer containing 0·5 μc. of uniformly-labelled ^{14}C-amino-acids and varying amounts of non-labelled L-amino-acids. Incubation was carried out at 37° in a Dubnoff metabolic shaker under a gas phase of 95 per cent oxygen–5 per cent carbon dioxide. After incubation, tissue and medium were separated by filtration through fine gauze and treated with trichloroacetic acid. Methods used for the extraction of amino-acids, the purification of liver protein, and the determination of radioactivity in these substances will be fully described in a subsequent report.

When liver slices were incubated in the presence of varying extracellular concentrations of one essential amino-acid, the rate of incorporation of another amino-acid into hepatic protein was altered (Table 1). Thus, as the initial extracellular concentration of phenylalanine was increased from subnormal plasma-levels (2 μM) to normal (50 μM) and supranormal (155 μM) values, radioactivity incorporated into protein from ^{14}C-leucine was significantly enhanced. Similar results were obtained when the initial extracellular concentration of threonine or valine was varied (Table 1). Column chromatographic separation of amino-acids in hydrolysates of hepatic protein revealed that radioactivity incorporated from ^{14}C-leucine was entirely in the form of this amino-acid.

Table 1. Effect of Initial Extracellular Level of One Amino-Acid on Uptake of ^{14}C-Leucine into Hepatic Protein

Amino-acid	Initial extracellular concentration (μM)	Incorporation c.p.m./mg protein	*P*
Phenylalanine	2	10·0 ± 0·8	
	50	11·4 ± 1·2	
	155	13·2 ± 0·8	< 0·01
Threonine	3	6·3 ± 0·2	
	228	8·2 ± 0·1	0·01
	500	9·5 ± 0·2	0·01
Valine	3	8·7 ± 0·1	
	157	10·2 ± 0·5	0·04
	338	16·3 ± 0·9	0·01

Liver slices were incubated for 15 min in the presence of 0·5 μc, (16 μM) of uniformly-labelled ^{14}C-leucine and varying amounts of another essential amino-acid. Normal plasma concentrations of the latter were as follows: phenylalanine, 50 μM; threonine, 228 μM; valine, 157 μM. After incubation, liver slices were homogenized in 5 per cent trichloroacetic acid. The precipitated protein was purified[6], air-dried, and counted at infinite thickness in Tracerlab '*TGC*-14' thin-window flow counter. Values are averages ± *S.E.M.* of 12 incubations with phenylalanine and 3 incubations each with threonine and valine.

The highest initial extracellular concentration of phenylalanine employed (155 μM) maintained normal or supranormal intracellular levels of this amino-acid over a 60-min incubation period (Table 2). Variations in phenylalanine levels appeared to have no effect on the distribution of leucine between cell and medium at the end of this period. However, the early flux[7] of leucine into the hepatic cell as well as the flux of phenylalanine were altered under these conditions. As anticipated[8], the highest concentration of phenylalanine greatly increased the flux of free phenylalanine (Table 2). In contrast, leucine exchange between extracellular and intracellular compartments was depressed. Therefore, the accentuated incorporation of leucine into protein under these conditions (Table 1) was apparently not due to increased availability of this amino-acid. Similarly, incorporation of ^{14}C-valine and ^{14}C-lysine into protein was increased at the highest concentration of phenylalanine even though the flux of these amino-acids into the cell was not significantly altered. Since alterations in the rate of incorporation of amino-acid into protein may not accurately reflect changes in protein synthesis or turn-over[9], measurements of the flux of leucine into hepatic protein were made. It was found that elevated levels of phenylalanine significantly enhanced the turn-over of hepatic protein. Thus, in a representative experiment the flux of leucine into hepatic protein during the 15- to 30-min interval of incubation was 22·2 μg/h/mg protein when the initial extracellular concentration of phenylalanine was 155 μM, but only 14·9 μg/h/mg protein with 50 μM phenylalanine.

Protein breakdown, as well as protein synthesis, was accentuated in the presence of supranormal levels of phenylalanine in medium and cell. For example, after incubation of hepatic slices for 60 min, 4·921 μmoles of essential amino-acids (excluding phenylalanine) were released from protein when the initial extracellular concentration of phenylalanine was 50 μM, whereas 5·342 μmoles were released when 155 μM phenylalanine was present. Larger increases in protein catabolism undoubtedly occurred at the supranormal level of phenylalanine (155 μM), since the accumulation of amino-acids was partially obscured by an increase in amino-acid

Table 2. Effect of Extracellular Level of L-Phenylalanine on Distribution and Flux of Free Phenylalanine and Leucine in Hepatic Tissue

Initial extracellular phenylalanine (μM)	Final phenylalanine concentration Liver (μmole/g)	Medium (μmole/ml.)	Final leucine concentration Liver (μmole/g)	Medium (μmole/ml.)	Flux Phenylalanine (mμmole/g/min)	Leucine
2	0·035	0·028	0·109	0·080	0·32	1·10
50	0·045	0·048	0·098	0·078		
155	0·141	0·115	0·122	0·082	14·34	0·75

Liver slices were incubated in the presence of 0·5 μc. each of uniformly labelled ^{14}C-phenylalanine and ^{14}C-leucine (16 μM) and varying amounts of non-labelled phenylalanine. Amino-acid content was determined in liver and medium after 60 min incubation using the Beckman model 120 automatic amino-acid analyser. Flux of free amino-acid was calculated over the 1·5–3 min period. Each value is a single determination on extracts combined from 3 incubations. Normal hepatic levels of amino-acid were 0·085 ± 0·005 μmole phenylalanine per g and 0·206 ± 0·017 μmole leucine per g of tissue. Radioactivity of amino-acids was measured directly on the column effluent of the amino-acid analyser employing a Packard scintillation flow detector.

utilization. Thus, the amount of ^{14}C-leucine remaining after incubation of hepatic tissue for 60 min in the presence of 155 μM phenylalanine was reduced about 15 per cent compared to that remaining in similar experiments with 50 μM phenylalanine.

These observations indicate that the degradative and synthetic aspects of protein metabolism were both stimulated in surviving hepatic tissue when the initial extracellular concentration of a single essential amino-acid was elevated. Secondary changes in uptake and distribution of other amino-acids between extracellular and intracellular liver compartments did not appear to be correlated with the alterations in protein turn-over. Information is not available to ascertain whether the primary effect of alterations in amino-acid levels on protein turn-over was on protein synthesis or protein breakdown.

Rapid Spectrophotometric Micromethod for Determination of Histaminase Activity

It is known that in biological systems histamine is broken down by histaminase[1]. In this reaction oxygen is consumed and hydrogen peroxide is formed. A manometric method of measurement[2] is based on the oxygen consumption and a chemical method[3,4] on the production of hydrogen peroxide. In the latter method indigo is added to the incubation mixture and the discoloration of this mixture by the hydrogen peroxide formed is a measure of the enzyme activity. This is due to the peroxidatic activity of catalase mostly present in the biological fluids or tissue extracts under test. The disadvantages of the chemical method are the long incubation period of 24 h and the necessity of at least 1 ml. of serum in the case of histaminase determinations in blood.

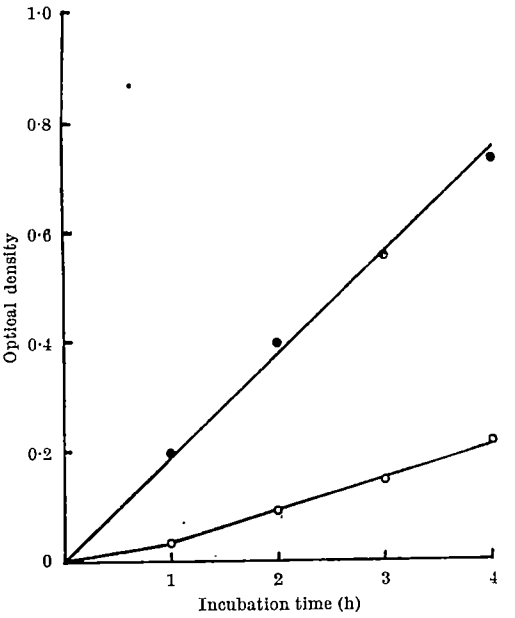

Fig. 1. Increase in optical density at 470 mμ of an incubation mixture of 1 ml. total volume, containing the phosphate buffer, *p*H 7·2, 0·1 ml. of rabbit plasma, 20 μg peroxidase, 50 μg ortho-dianisidine and 10^{-2} M histamine dihydrochloride (upper curve). The lower curve is related to a mixture without added histamine dihydrochloride

In our experiments with small animals this amount of serum makes it impossible to estimate histaminase activity repeatedly in the blood of the same animal. Therefore, we needed a more sensitive method, which was obtained by using ortho-dianisidine instead of indigo as a hydrogen donor. With this reagent it is possible to start the incubation with a colourless mixture. The increase in optical density during incubation is a measure of the histaminase activity. Moreover, we added peroxidase to the incubation mixture to be independent of the peroxidatic activity of the sample to be tested.

The reagents used were: (1) 0·1 M phosphate buffer, *p*H 7·2; (2) 2×10^{-1} M histamine dihydrochloride solution; (3) 4 mg of peroxidase (Boehringer) dissolved in 10 ml. of distilled water; (4) a solution of ortho-dianisidine in 96 per cent alcohol (1 mg/ml.).

An incubation mixture of 1 ml. containing the buffer, 0·05–0·1 ml. of the test sample and 0·05 ml. of the reagents 2, 3 and 4 was prepared on ice in a 10-mm light pass cell of a Beckman spectrophotometer. After measuring the optical density at 470 mμ the mixture was incubated at 25° C. The intensity of the resulting colour was determined at intervals of 1 h.

With this method it is possible to determine histaminase activity in samples of 0·05–0·1 ml. of plasma within a period of 4 h. The slope of the upper curve in Fig. 1 shows the increase in optical density of an incubation mixture to which 0·1 ml. of rabbit plasma had been added. The lower curve relates to a mixture with the same amount of rabbit plasma but without added histamine (reagent 2) and demonstrates that there is still some increase in optical density. This is most likely due to the presence of histamine in the sample of plasma. This may indicate that this method is also suitable for determining histamine. In this case the substrate instead of the enzyme will be the limiting factor in the reaction.

Prevention of Fatty Liver by Administration of Adenosine Triphosphate

It has recently been shown that the fatty liver produced in rats by ethionine administration is associated with a decrease in hepatic adenosine triphosphate (ATP) levels and that injections of ATP are able to prevent both the fatty liver and the drop in ATP[1,2]. We have observed that a variety of agents which produce a fatty liver lead to decreased ATP concentrations in the liver and that the protective effects of ATP administration are not limited to ethionine toxicity.

Investigations were conducted with three hepatotoxic drugs in addition to ethionine, namely: ethanol, carbon tetrachloride and azaserine. It is well known that the administration of ethanol and carbon tetrachloride to animals leads to the production of a fatty liver; the antibiotic azaserine (*o*-diazoacetyl-L-serine) is able to produce a fatty liver as well as liver cell necrosis[3,4].

Female albino Sprague–Dawley rats weighing 150–200 g were fasted overnight and divided into four different groups: (1) control; (2) control plus ATP; (3) hepatotoxic drug; (4) hepatotoxic drug plus ATP. Details of the dosage schedules and routes of administration are outlined in Table 1. The animals were killed after times which were sufficient to lead to accumulation of fat in the liver—namely, 3 h for azaserine, 5 h for carbon tetrachloride, 6 h for ethionine and 10 h for ethanol. Liver tissue was assayed for ATP by the luciferin-luciferase method[5] and for triglycerides (after extraction and fractionation of lipids) by the method of Van Handel and Zilversmit[6].

Table 1 shows the hepatic levels of ATP and triglyceride under the various experimental conditions. It will be seen that a fatty liver was produced by each agent. Ethionine treatment produced the highest hepatic triglyceride levels (21 mg/g), while the degree of lipid accumulation produced by the other agents was somewhat less (approximately 17 mg/g). In all cases, hepatic levels of ATP decreased. This decrease was 82 per cent with ethionine, 52 per cent with carbon tetrachloride and approximately 37 per cent with ethanol and azaserine. Injections of ATP together with these agents prevented both fat accumulation and decreases in hepatic ATP levels. The results (Table 1) were all highly significant statistically.

It will also be noted that in control animals the administration of ATP served to elevate hepatic ATP concentrations with a concomitant decrease in hepatic triglyceride content. Animals fed mineral oil showed a definite increase in liver triglycerides compared to saline ($P < 0.005$) or glucose ($P < 0.005$) controls. The mechanism of this latter effect, observed on previous occasions in this laboratory, is obscure.

The question arises as to the manner whereby the injected ATP raises hepatic ATP levels. Since it is generally believed that ATP as such does not cross cell membranes, it is likely that the ATP is first hydrolysed, after which the nucleoside derivatives enter the cell and are then converted back to ATP. Whatever the mechanism whereby the cellular ATP levels are elevated by ATP administration, we cannot yet conclude that such cellular levels *per se* are directly related to the prevention or amelioration of the fatty infiltration by the agents used in the work recorded here.

We have indeed obtained evidence in carbon tetrachloride- and azaserine-treated animals that precursors of ATP, such as adenosine-5′-monophosphate and inosine, can raise hepatic ATP levels without protecting against the development of fatty liver. Furthermore, azaserine-treated rats given nicotinamide injections do not develop fatty livers and yet the hepatic ATP levels remain subnormal.

The effects of ATP administration on hepatic lipid metabolism could be mediated by a variety of mechanisms. In view of the importance of synthesis and secretion of lipoproteins in the transport of lipids out of the liver, interference with hepatic protein synthesis could readily lead to the development of a fatty liver[7]. Indeed, in the case of carbon tetrachloride[8] and puromycin[9], this is believed to be the major mechanism for production of the fatty liver by these agents. Farber *et al.*[1,2] likewise have suggested that the ethionine-induced fatty liver is due to impaired protein synthesis secondary to the depletion of ATP levels by the formation of *S*-adenosyl-ethionine. They postulate therefore that injections of ATP prevent the cellular depletion of ATP produced by ethionine and thus prevent the fatty liver. However, in the case of ethanol and azaserine there is no direct evidence implicating impairment of protein synthesis as the major mechanism for the fatty liver produced by these agents. While ethanol can be shown to inhibit hepatic secretion of lipoproteins, this occurs only at very high concentrations[10] and hence this is unlikely to be a phenomenon of major importance.

It is quite possible that ATP administration to animals may exert protective effects by indirect means. ATP injections may shock the animal and predispose to the

development of hypothermia[11]. The possibility that hypothermia might play an important part in protecting the liver against carbon tetrachloride was suggested by observations on chordotomized[12] and adrenalectomized[13] animals. We have found that animals treated with carbon tetrachloride or ethanol, together with ATP injections, become hypothermic, and this may be a factor in the protection afforded by ATP in these animals. However, hypothermia has not occurred in our experiments in which ethionine and ATP, or azaserine and ATP, were given. Work is now in progress to elucidate further the mechanisms for the protective action of ATP administration on the production of fatty livers in the experimental animal.

Differential Analysis by Various Staining Techniques of Structures present in Developing Spermatids of the Silkworm

In the course of an electron microscope investigation[1] of spermiogenesis in the silkworm, *Bombyx mori* Linné, the formation of a tubular structure and two bands have been detected in the developing spermatids fixed with potassium permanganate or osmium tetroxide, which have not, to our knowledge, been reported previously from light microscopic investigations[2–7]. The two bands, which run parallel with the developing spermatid nuclei, were found to be of equal density when the material was fixed with osmium tetroxide, while one of them was less dense when the material was fixed with potassium permanganate.

Testes of the fifth larval instar of silkworm were immersed for 1–2 h in 1 per cent osmium tetroxide or potassium permanganate buffered to *p*H 7·4 with veronal–acetate buffer. When the specimens were fixed, they were dehydrated in a series of increasing concentrations of ethyl alcohol, and embedded in a mixture of methyl and *n*-butyl methacrylates or in 'Epon' epoxy resin. Sections were cut with the Porter–Blum's microtome equipped with a glass knife. They were examined in *JEM-T6* or *TRS-E*$_1$ electron microscopes.

Fig. 1 shows a cross-section of a developing spermatid, fixed with potassium permanganate, at the level of the nucleus, in which the fine granular nucleus (*N*) enveloped with the dense nuclear membrane is found to be almost completely surrounded by the elongated endoplasmic

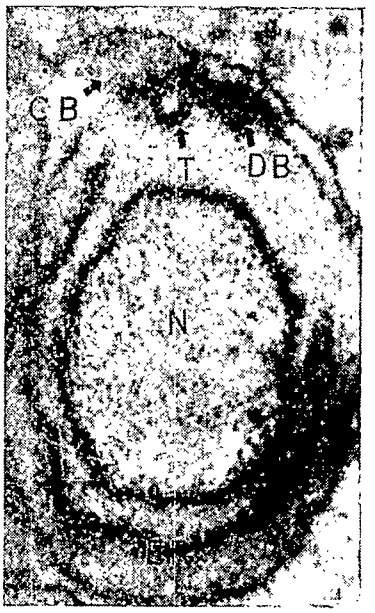

Fig. 1. ×45,000

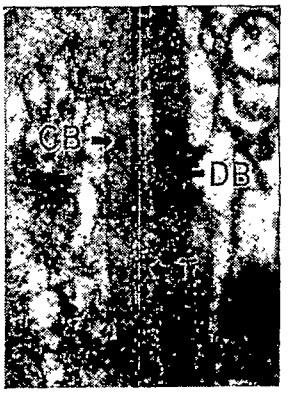

Fig. 2. ×23,000

reticulum (*ER*). A tubular structure (*T*) is attached to the plasma membrane, and a dense amorphous substance (*DB*) can be seen at the periphery of the cytoplasm. The less-dense amorphous substance (*CB*) appears to be attached to the plasma membrane, but is situated outside the cell. Fig. 2 shows a longitudinal section of the developing spermatid, fixed with potassium permanganate, through the tubular structure (*T*) to which belong the dense (*DB*) and the less-dense bands (*CB*). These bands correspond, respectively, to the dense and less-dense substances which can be seen in Fig. 1. Fig. 3 shows a cross-section of the developing spermatid nucleus fixed with osmium tetroxide at the level higher than that in Fig. 1. The nucleus (*N*) is filled with dense filamentous elements approximately 100 Å in diameter. The tubular structure (*T*) is clearly visible, but the clear band (*CB*) outside the cell cannot be distinguished from the dense band (*DB*). Fig. 4 shows an oblique longitudinal section of the developing spermatids fixed with osmium tetroxide, showing a small part of the nucleus (*N*). The clear band (*CB*) being outside the cell appears to be too dense to identify it from the dense band (*DB*). The tubular structure (*T*) can be seen here as a spindle-shaped structure. The clear and dense bands are always identifiable in cross-sections of developing spermatids but cannot always be seen in longitudinal sections. However, serial sections reveal that the bands run parallel with the developing spermatids from the base to the top of the conical head.

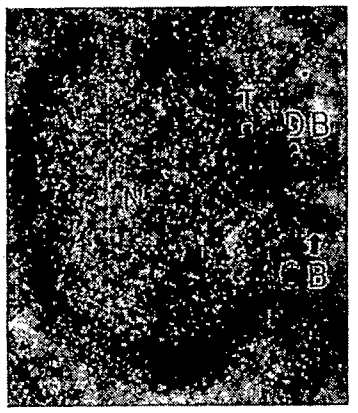

Fig. 3. ×40,000

Fig. 4. ×37,000

The present investigations emphasize the point that the ultra-structure of cellular components should be observed with various fixatives. In the present case, two structures which at first appeared to be similar due to their density being the same on osmium tetroxide-fixation appeared differently on potassium permanganate-fixation.

Catalase Activity of a Crude Enzyme Preparation from Iron-chlorotic Barley (*Hordeum vulgaris*) Seedlings

We have reported that air ions of either charge accelerate the development of iron chlorosis in barley seedlings (*Hordeum vulgaris* var. California 'Mariout') cultivated in an iron-free nutrient solution[1–3]. During the course of experiments undertaken to explore the mechanisms involved in this phenomenon, we observed that the addition of iron in the form of iron–potassium–ethylene-tetraacetate (Fe-EDTA) to cell-free extracts prepared from barley seedlings which had developed chlorosis as the result of growth in an iron-free culture medium in a normal atmosphere produced a marked increase in the catalase activity of the extracts. The results presented here indicate that the pattern of increase in catalase activity is related to the extent of chlorosis.

Seedlings of barley were raised in an iron-free chemically-defined nutrient solution under greenhouse conditions. The details of the plant growth system are described in earlier papers[1–4], and we have used these same methods here. The essentials are: germinated seeds raised in a nutrient solution without an iron source for 7 days. By this time the seedlings attained a length of about 12 cm without developing visible signs of chlorosis. One third of the seedlings designated 'non-chlorotic seedlings' were collected at this time. By the 15th day severe chlorosis appeared in the remaining seedlings, and half of them—'severe chlorotic seedlings'—were gathered. At this point 5 p.p.m. of iron in the form of Fe-EDTA[5] was added to the culture medium. By the 30th day the seedlings had recovered completely from iron chlorosis. All of them were collected and were designated 'recovered seedlings'.

Because of their more abundant content of catalase, only the aerial parts of the collected seedlings were used in the present experiments. The extraction procedures used were modifications of those developed by Kotaka[6]. The aerial parts were washed thoroughly with distilled water; excess water on the surface of the seedlings was removed with tissue paper and the fresh weight was determined. The plant tissue was cut into small pieces with scissors and ground in a mortar with a small amount of quartz sand and a small volume of M/15 phosphate buffer at *p*H 6·8. The homogenate was squeezed through 8 layers of cheese-cloth and the pulp was ground again with a small amount of phosphate buffer. This process was repeated until the pulp was free from chlorophyll. The total volume of filtrate was adjusted to 10 times its fresh weight, allowed to stand at 4° overnight and then was centrifuged at 3,000*g* for 10 min. The supernatant obtained was used as the enzyme solution.

Enzyme protein was determined by the method of Sutherland *et al.*[7]. Catalase activity was determined as follows: to 9 ml. of substrate (0·01 N H_2O_2 in M/15 phosphate buffer, *p*H 6·8) 1 ml. of enzyme preparation was added. The reaction mixture was incubated at 25° for exactly 5 min. At the end of this time, 10 ml. of 2 N H_2SO_4 was added in order to stop the reaction. For a blank control, 1 ml. of enzyme preparation was added to a flask containing 9 ml. of 0·01 N H_2O_2 in M/15 phosphate buffer, *p*H 6·8, and 10 ml. of 2 N H_2SO_4. In both solutions the residual H_2O_2 was titrated with 0·05 N $KMnO_4$. The amount of H_2O_2 decomposed was calculated by the subtraction of the value at 5 min from that of the blank control. The catalase activity was expressed as mg of H_2O_2 decomposed/mg enzyme protein/5 min. The catalase assay was performed in duplicate.

Fe-EDTA prepared by the method of Jacobson[5] was so diluted with the phosphate buffer that it provided a final iron concentration of 50 p.p.m. when added to an equal volume of test solution. Twenty ml. of enzyme preparation, which was diluted with the phosphate buffer if necessary, was incubated in a water bath at 25° for 10 min, then 20 ml. of the diluted Fe-EDTA was added to the enzyme solution. This mixture was designated 'Fe-enzyme mixture'. Immediately after mixing, 1 ml. of the iron-enzyme mixture was pipetted into 9 ml. of the substrate solution and the titration of H_2O_2 was conducted as already outlined here. This value of H_2O_2 decomposed was designated 't_0 activity'. A blank reading was also taken at this time. Thereafter the catalase activity of the iron-enzyme mixture was determined at stated intervals. From each reading at a given incubation time, the t_0 reading was subtracted. The differences obtained were defined as the increment in catalase activity.

As a control an equal volume of M/15 phosphate buffer, *p*H 6·8, was added to 20 ml. of enzyme preparation after 10 min pre-incubation. In order to test H_2O_2 decomposition by Fe-EDTA, another control was provided consisting of 20 ml. of the diluted Fe-EDTA added to 20 ml. of M/15 phosphate buffer, *p*H 6·8. The catalase activity of this mixture was determined at intervals by the method already described here. No decomposition of H_2O_2 was detected throughout the period of incubation.

The activity of the enzyme preparation made from non-chlorotic barley was not increased by adding 50 p.p.m. iron (Fig. 1), although its initial catalase activity was the highest of those tested. The extract from severe chlorotic barley showed a marked increase in catalase activity after the addition of Fe-EDTA (Fig. 2). The peak of activity appeared at 120 min and was followed by a well-defined decrease. The initial catalase activity of this preparation was the lowest of those tested. In the case of recovered seedlings the increase in catalase activity reached its maximum after 120 min incubation and remained at this level for the entire 6-h period of observation (Fig. 3). Presumably the increased activity may last beyond that period. The catalase activity of this preparation was slightly lower than that made from non-chlorotic seedlings.

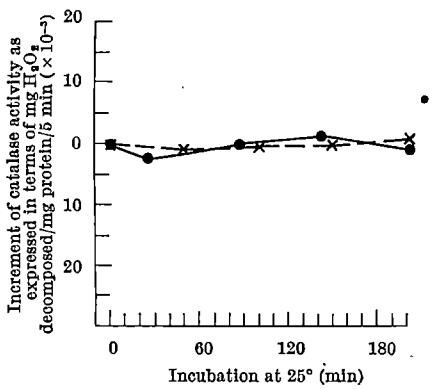

Fig. 1. Effect of Fe-EDTA on catalase activity of enzyme preparation from non-chlorotic barley seedlings
●, Enzyme preparation + Fe-EDTA in phosphate buffer; ×, enzyme preparation + phosphate buffer

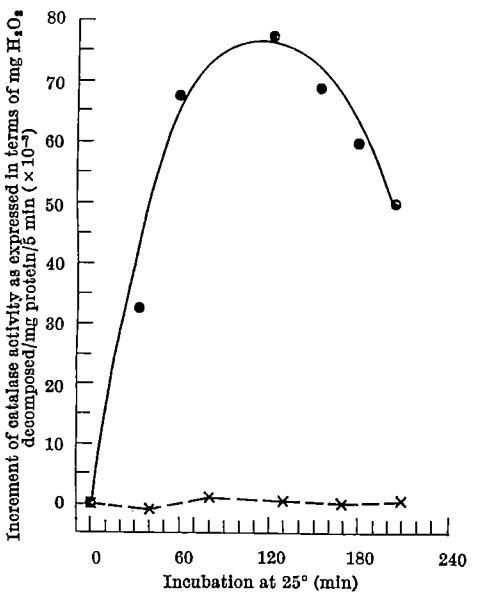

Fig. 2. Effect of Fe-EDTA on catalase activity of enzyme preparation from severe chlorotic barley seedlings
●, Enzyme preparation + Fe-EDTA in phosphate buffer; ×, enzyme preparation + phosphate buffer

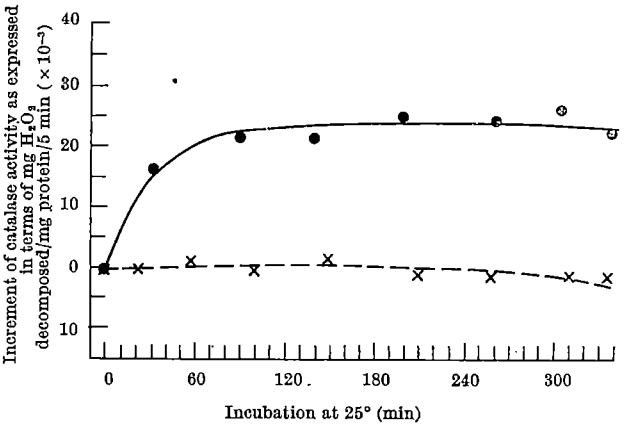

Fig. 3. Effect of Fe-EDTA on catalase activity of enzyme preparation from recovered barley seedlings
●, Enzyme preparation + Fe-EDTA in phosphate buffer; ×, enzyme preparation + phosphate buffer

It is curious that extracts prepared from chlorotic barley seedlings react with Fe-EDTA to produce a large increase in catalase activity while those made from normal seedlings fail to do so. This property of reactability seems to decline as the plants recover from chlorosis (Fig. 3). The simplest explanation of the phenomenon would be to assume that chlorotic plants develop an incomplete catalase which reacts with Fe-EDTA to form catalase. However, the results are equally explicable on the assumption that some sort of inhibitor is involved, for example, crude enzyme preparations from normal plants contain catalase + inhibitor while chlorotic plants in addition produce a substance which promotes a reaction between Fe-EDTA and the inhibitor, thereby releasing catalase. Various other possibilities exist but, until we have more experimental data, serious speculation about which one is correct appears unwarranted.

Treatment of Seeds with Ethylmethansulphonate and Diethylsulphate

Following Heslot's discovery of the strong mutagenic action of diethylsulphate (DS) and ethylmethansulphonate (EMS) in barley[1], techniques for the use of aqueous solutions of both compounds in mutagenic experiments have been investigated by some workers[2,3].

Table 1

	Ki, 20° C (l.mole^{-1} min^{-1})	*Ki*, 10° C (l.mole^{-1} min^{-1})	*Ki*, 5° C (l. mole^{-1} min^{-1})	*E* (kcal/ mole^{-1})
Diethylsulphate	$3{\cdot}600 \times 10^{-5}$	$1{\cdot}102 \times 10^{-3}$	$0{\cdot}625 \times 10^{-3}$	18·87
Ethylmethansulphonate	$0{\cdot}110 \times 10^{-3}$	$0{\cdot}035 \times 10^{-3}$	$0{\cdot}015 \times 10^{-3}$	21·32

tion depends only on the amount of ester absorbed and not on the treatment technique, a series of tests were carried out. The results are shown in Table 4.

It is concluded that it is possible to compare the effects of two different substances on the same material, as well as the sensitivity of different biological materials with respect to the same agent, only when the treatment is carried out in controlled conditions and the amount of the active substance absorbed is measured.

Table 4. Germination of *durum* Wheat, var 'Cappelli', treated under Different Experimental Conditions leading to the Absorption of the Same Amount of Ester (5×10^{-5} moles/seed)
(The absorption of the acid is below the toxicity threshold)

Temperature	Treatment Time	DS moles/litre	Germination (control = 100)
15° C	4 h	$23{\cdot}01 \times 10^{-3}$	$64{\cdot}3 \pm 2{\cdot}2$
20° C	12 h	$7{\cdot}67 \times 10^{-3}$	$67{\cdot}4 \pm 1{\cdot}1$
25° C	4 h	$7{\cdot}67 \times 10^{-3}$	$67{\cdot}1 \pm 2{\cdot}1$
30° C	2 h 50′	$7{\cdot}67 \times 10^{-3}$	$66{\cdot}6 \pm 1{\cdot}2$

It is well known that these alkylating substances, in solution, hydrolyse. We have measured the hydrolysis constants and the activation energy of EMS and DS, and the results are shown in Table 1: it can be seen that the stability of the solutions of the two substances is sharply different. This difference must necessarily affect the process of absorption into the seeds of the compounds and of their hydrolysis products.

Measurements of absorption into the seeds of the non-hydrolysed substances and of the hydrolysis products were carried out as described in a previous paper[4]. The results obtained for the absorption of DS on fodder pea, var. 'Parvus', and on *durum* wheat, var. 'Cappelli', and for EMS on *durum* wheat, var. 'Cappelli', are shown in Tables 2 and 3.

Since the acidic products of hydrolysis can have a negative effect on germination, it was necessary to ascertain the minimum amount of acid which could be absorbed by seeds without damage. This threshold, measured by the method described in our previous work[4] for *durum* wheat, var. 'Cappelli', amounts to 8×10^{-8}, and to 13×10^{-8} absorbed moles/seed for $C_2H_5OSO_3H$ and CH_3SO_3H, respectively. On fodder pea, var. 'Parvus', the threshold was measured only for $C_2H_5OSO_3H$ and was found to amount to 580×10^{-8} absorbed moles/seed.

In order to demonstrate that, when the acid is absorbed below the threshold concentration, the effect on germina-

Auxin Activity of Certain Oximes

In auxin studies on compounds not possessing a carboxyl group Wain found, in this laboratory, that 2 : 3 : 6-trichlorobenzaldoxime exhibits activity as a plant growth regulating substance. At his suggestion other oximes were investigated by the writer and Mr. P. Cozens, and 3-indolylacetaldoxime and 2 : 4-dichlorophenoxy-acetaldoxime were also found to be active (Table 1). Further work was then undertaken to determine whether these aldoximes are active *per se* or if they undergo metabolism in plant tissues to yield active substances.

While this study was in progress, chromatographic evidence was reported for the conversion of 3-indolylacetaldoxime to 3-indolylacetonitrile and 3-indolylacetic acid (IAA) in fungi and banana leaf tissue[1], results which are of interest with respect to the 'Indole Cycle'[2]. The conversion of 2 : 6-dichlorobenzaldoxime to 2 : 6-dichlorobenzonitrile by soil micro-organisms has also been reported; such conversion in higher plants, however, was not established[3].

The metabolism of certain aldoximes in plant tissue has now been studied by exposing solutions of each compound to wheat coleoptile or pea stem segments followed by chromatographic analysis of the products, using chromogenic reagents and standard bioassay techniques[4].

The aldoximes were readily separated from their corresponding carboxylic acids by chromatography using Whatman No. 1 paper and *n*-butanol : ammonium hydroxide : water (100 : 3 : 18) as solvent. 3-Indolylacetaldoxime ($R_F = 0{\cdot}89$), after metabolism in wheat or pea tissue for 48 h, yielded an acidic product that gave marked auxin activity in the chromatogram segments which corresponded with the position of IAA ($R_F = 0{\cdot}28$).

Table 1. PLANT GROWTH-REGULATING ACTIVITY OF OXIMES AND THEIR CORRESPONDING ACIDS IN THE WHEAT CYLINDER, PEA SEGMENT AND PEA CURVATURE TESTS

2 : 3 : 6-Trichlorobenzaldoxime	100	98	110‡	120*	100	101	101	104	0	0	0	0
3-Indolylacetic acid	117*	139*	157*	160*	106†	121*	127*	130*	1	2	3	5
3-Indolecarboxylic acid	101	100	99	98	101	101	102	103	0	0	0	0
2 : 4-Dichlorophenoxyacetic acid	106	118*	153*	159*	105†	114*	124*	125*	1	4	6	6
2 : 3 : 6-Trichlorobenzoic acid	99	103	121*	150*	100	109†	124*	128*	0	1	4	5

Control measurements: wheat test 100; pea segment test 100; pea curvature test 0. For details of these tests see ref. 4.
Results in wheat cylinder and pea segment tests significantly different from water control: * at 0·1 per cent level; ‡ at 1 per cent level; † at 5 per cent level.

Furthermore, the chromogenic reactions with Ehrlich, Salkowski and nitric/nitrous acid reagents were identical to those obtained with IAA.

Similar results were also obtained when 2 : 4-dichlorophenoxy-acetaldoxime ($R_F = 0{\cdot}96$) was treated with wheat and pea tissue, the highly active acidic product being identified as 2 : 4-dichlorophenoxyacetic acid by bioassay and chromogenic reagents ($R_F = 0{\cdot}52$).

The above results therefore establish the conversion of these aldoximes to the corresponding carboxylic acids in wheat and pea tissue metabolism. It is also most likely that the auxin activity shown by these oximes is dependent on this conversion within the cells of the test material. When the auxin activity of the respective oximes and acids is considered, the inactivity of 3-indole-aldoxime is not surprising since the expected product of metabolism, 3-indolecarboxylic acid, is inactive (Table 1).

The significant auxin activity of 2 : 3 : 6-trichlorobenzaldoxime in the wheat cylinder test contrasts with its inactivity in the pea tests. Evidence was obtained in metabolism experiments confirming that wheat tissue converts 2 : 3 : 6-trichlorobenzaldoxime to 2 : 3 : 6-trichlorobenzoic acid, whereas with pea tissue this was not the case. Further examination of this interesting difference in the behaviour of wheat and pea tissue with 2 : 3 : 6-trichlorobenzaldoxime is proceeding.

Volatile Amines as Components of Toasted Oat Flakes

DURING the toasting process of oat flakes a number of components influencing their organoleptic properties are developed. Some of them escape with the steam; others are non-volatile. Among the non-volatile components the carbonyl compounds predominate[1]. It is, however, interesting that during the toasting process amines, a number of sulphur compounds and other so far unidentified compounds are also formed. For isolation, the volatile compounds obtained in processing were transferred to corresponding chlorides. On purifying the samples to be examined, the amines were separated by means of paper chromatography and identified by their standards, R_F values and by means of the necessary agents.

Table 1. AMINES AS COMPONENTS PRESENT IN TOASTED OAT FLAKES

Spot	Amine	R_F value	Relative amount of component	Colour

15	Amylamine	0·71	+ + +	violet

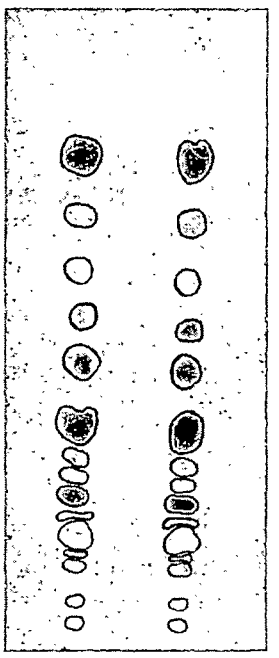

Fig. 1. Chromatogram of volatile amines present in toasted oat flakes. Solvent system, *n*-butanol–glacial acetic acid–water (4 : 1 : 5); developing time 24 h; detection by ninhydrin

Analytical results showed that during the toasting process of flakes a variety of amines was formed. In accord with the supposed formation the aliphatic amines C_1–C_5 are present, constituting the major part of the total amount. The diamines are represented in relatively small amounts by putrescine, cadaverine and 1,3-diaminopropane. Of the polyamines, *NN'*-di-1,4-diaminobutane is present in traces. The small amount of ethanolamine apparently originates by the splitting of phospholipid, probably cephalin. Of the secondary amines, dimethylamine present in traces was identified.

PHYSIOLOGY

Minimal Salt Load required to induce Secretion from the Nasal Salt Glands of Sea Gulls

Most investigators[1–3] examining the function of the avian nasal salt gland have used a salt load consisting of 1 g NaCl/kg body-wt. administered either intravenously or orally. This form of osmotic stimulation will promptly induce secretion of a hypertonic solution of NaCl, ranging in concentration from 400 to 1,200 m.equiv. NaCl/l., from the salt gland. Nechay, Larimer and Maren[4] were able to induce secretion from the salt glands of ringbilled (*Larus delawarensis*) and herring (*Larus argentatus*) gulls by constantly infusing at the rate of 0·6 ml./kg/min a salt load of 1·8–7·2 m.mol. This work is reported here since so far there has been no other information concerning the interrelationship of body-weight and the minimum amount of salt required to induce secretion from the salt gland.

A group of 17 gulls captured along the northern California coast were used. Five glaucous-winged (*Larus glaucescens*), six western (*Larus occidentalis*), three herring (*Larus argentatus*), and three California (*Larus californicus*) gulls were in the group. The birds were maintained in a flight cage and given canned dog food periodically supplemented with frozen white bait to eat and fresh water to drink. The wing vein was cannulated with a short piece (about 8 in.) of 'Teflon' tubing (A.W.G. No. 22). The gulls were gently restrained by securing the wings with masking tape, supporting the body on a V-shaped wooden trough, and clamping the head to prevent head-shaking. An initial blood sample was drawn into a heparinized syringe, and the 'Teflon' tubing was then connected to a burette containing a 10 per cent NaCl solution. The salt solution was infused at rates varying from 0·15 to 0·65 ml./min, stopped with the first drip of nasal fluid and the volume infused recorded. The drips of nasal fluids were counted and collected for analysis into a 50-ml. conical plastic test tube placed just under the tip of the bill. A second heparinized blood sample was taken after stopping the infusion, and both blood samples were centrifuged and the plasma taken for analysis. All fluid voided from the cloaca during the experimental period was collected for analysis. The concentration of sodium and potassium in the plasma, nasal fluid and cloacal fluid was determined with a Baird-Atomic internal standard flame photometer and that of chlorine using a Buchler–Cotlove chloridometer.

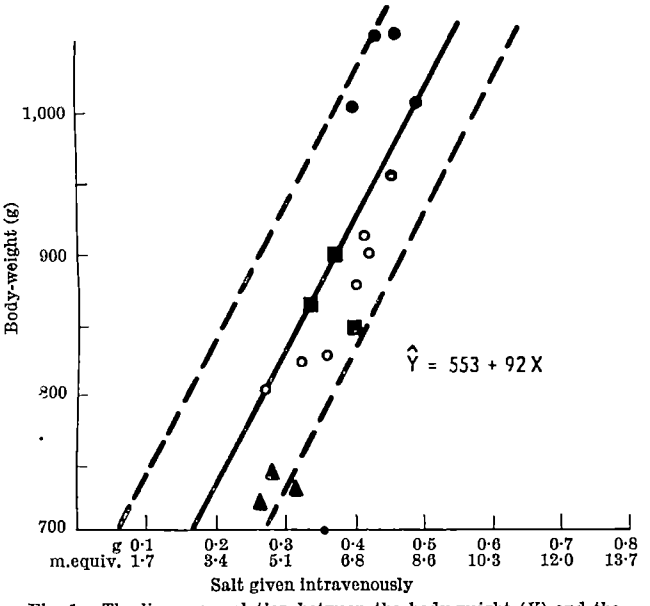

Fig. 1. The linear correlation between the body-weight (Y) and the minimum amount of salt (X) necessary to stimulate salt gland secretion in gulls. The scatter of the data is shown by the dotted lines. Solid circles, glaucous-winged gulls; open circles, western gulls; solid squares, herring gulls; solid triangles, California gulls

A striking linear correlation was found between the body-weight of the gulls studied and the minimum volume of 10 per cent NaCl solution required to initiate salt gland activity (Fig. 1). There was a tendency for the larger, more marine glaucous-winged gulls to require slightly less salt to induce secretion while the smaller, more freshwater California gulls required slightly more than average. The insignificant differences, however, between the responses of the various species of gulls justified considering them as a single group.

The data indicate, for example, that a 1-kg gull would require a minimum of 0·49 g of NaCl (with a scatter of 0·36–0·58 g) to stimulate secretion from the salt gland, or approximately half the 1-g level used by the other workers cited[1–3].

The secretory pattern of the salt glands activated by a minimum salt load showed some variation between gulls, the first drip occurring 5–24 min after starting the infusion and seemingly directly dependent on the rate of infusion. The maximum number of drips/min varied from 1·2 to 5·8, and the duration of secretion lasted 60–120 min. A typical secretory pattern is shown in Fig. 2. Notice that the maximum drip rate is reached rapidly, in all cases within 2–10 min after secretion commenced. The drip rate then falls off rather acutely during the next 10–20 min, levelling off and eventually stopping.

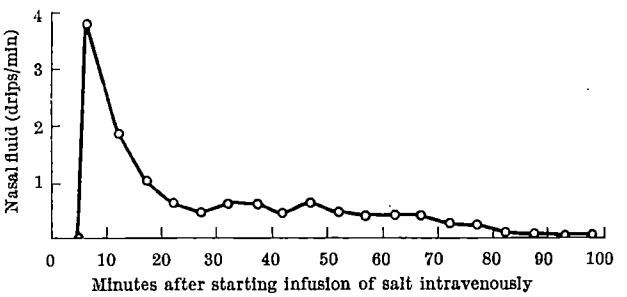

Fig. 2. Typical secretory pattern observed from a western gull (*SG* 243) receiving a minimal salt load

Following the minimal salt load the mean concentration of plasma sodium was elevated 21 m.equiv./l., the chlorine concentration was elevated 30 m.equiv./l., whereas the concentration of potassium was decreased 1 m.equiv./l. (Table 1). The concentrations of sodium, chlorine and potassium in the nasal fluid was approximately 4–5 times that noted in the plasma (Table 1) and are similar to values noted in gulls by other workers[1,3–6]. The gulls discharged the cloaca infrequently during the experiment and usually only once during the period of infusion. The electrolyte concentrations found in the cloacal discharge (Table 1) do not indicate that the kidney is concentrating at a maximum capacity, since the gull's kidney is able to eliminate about 300 m.equiv. NaCl/l. (ref. 5).

Table 1. Electrolyte Concentrations in Plasma, Nasal Fluid and Cloacal Discharge following a Minimal Salt Load in Sea Gulls which stimulates the Activity of the Salt Gland

Electrolyte	Plasma during salt gland inactivity	Plasma during salt gland activity	Nasal fluid	Cloacal discharge
Na	169 ± 4	190 ± 3	783 ± 63	184 ± 14
Cl	124 ± 1	154 ± 5	690 ± 36	191 ± 8
K	5·5 ± 0·8	4·5 ± 0·6	32·8 ± 2·6	18·2 ± 4·8

Values are expressed as the mean m.equiv./l. ± *S.E.*

It was not surprising to find a linear correlation between the body-weight of a gull and the minimum amount of salt required to induce salt gland activity, since food and water intake and metabolism are dependent on the size of an animal, and the primary function of the salt gland

is to eliminate the excess salt accumulated in these processes. How the salt load stimulates salt gland activity is uncertain. It is thought that osmoreceptors located probably in the central nervous system respond to the increased salt concentration[5], and this in turn causes the parasympathetic fibres innervating the salt gland to release acetylcholine, which is primarily responsible for stimulating salt gland secretion[1].

In the work recorded here an average increase in osmotic tension in the plasma of 21 m.equiv. Na/l., the difference between plasma sodium before and after salt loading (Table 1), was required to stimulate the central nervous system and salt gland activity. In the experiment of Nechay, Larimer and Maren[4] an increased osmotic load of 27 m.equiv. Na/l. was necessary to stimulate the glands. Wolf[7], investigating the stimulation of thirst in man and dogs by infusing hypertonic NaCl, concluded that a cellular shrinkage of 1–2 per cent resulting from the elevated osmolarity was required to initiate drinking. Later, Fitzsimons[8] infused rats not only with hypertonic NaCl but also sucrose, Na_2SO_4 and urea, and found that an increased osmotic tension of about 2 per cent was needed to initiate drinking. Therefore, the initial stimulus for the osmoreceptors of the central nervous system regulating the secretion of the salt gland is probably brought about by cellular shrinkage caused by the increased osmolarity associated with the elevated intravascular NaCl concentration which approximated 10 per cent in this investigation. Furthermore, the minimal stimulus required to induce the elimination of salt from the sea-gull is approximately 5 times that required to induce drinking in mammals.

A dramatic change in blood volume is also associated with the intravascular injection of salt. Assuming the blood volume of these gulls approximates 8·3 per cent of their body-weight and their hæmatocrit is 49 per cent[9], a 1-kg gull would have 83 ml. of blood and 40 ml. of plasma. The addition of 8·4 m.equiv. NaCl (0·5 g NaCl) to the blood would increase the plasma concentration of sodium by 210 m.equiv./l. since an average of only 21 m.equiv. Na/l. (or 10 per cent) was noticed in the plasma after salt loading; 90 per cent of the sodium was either lost by diffusion or the blood volume increased in order to dilute the added salt. A change in blood volume by as much as 80 per cent has been observed within 15 min after injecting a salt load of 0·5 g into gulls[9].

Rhythmic Urinary Excretion of Amphetamine in Man

The urinary excretion of amphetamine in man has been previously examined, both with regard to the elimination kinetics[1,2] and the total amount of unchanged drug excreted[1–9]. However, the majority of assay procedures adopted were non-specific, and no detailed investigation on the excretion kinetics of amphetamine, using a specific method of assay, appears to have been published.

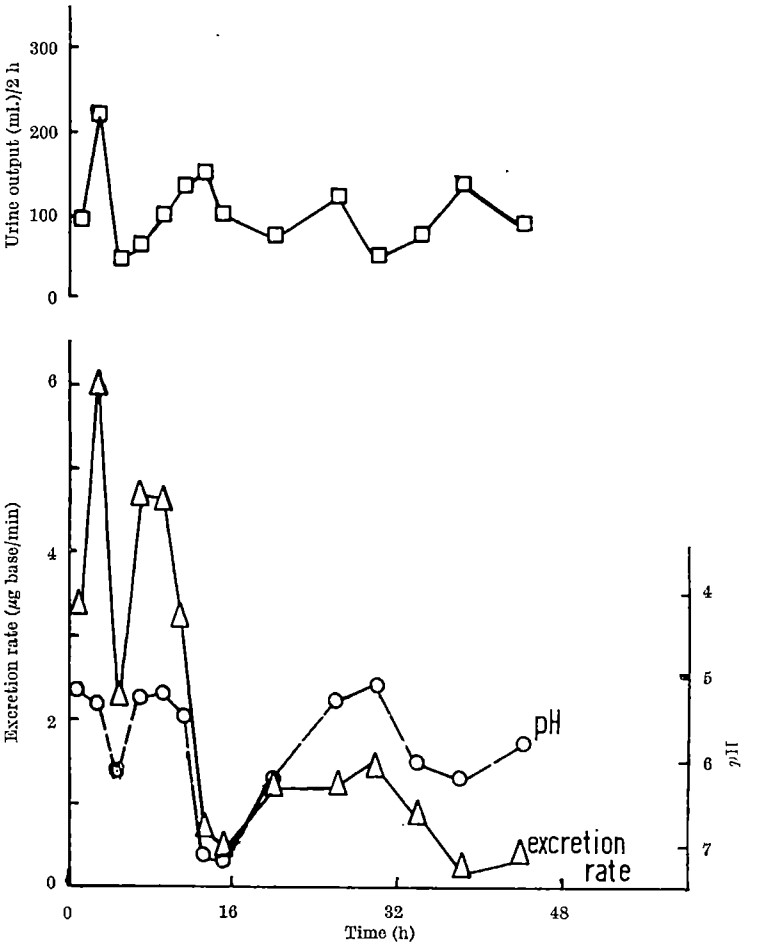

Fig. 1. Effect of urine *p*H and urine output on the urinary excretion of amphetamine in man, after oral administration of 10 mg (+)-amphetamine sulphate

This communication gives results obtained when 5–15 mg amphetamine sulphate were administered orally to male subjects. The elimination of the unchanged drug in the urine was determined by a specific assay procedure, based on gas-liquid chromatography[10]. Large fluctuations in the excretion rate of (+)- or (−)-amphetamine were observed, for example, Fig. 1, during drug excretion in all subjects examined. Different diets did not affect the pattern substantially. The total amount of unchanged amphetamine excreted in 48 h was 15–40 per cent or 30–66 per cent on giving (+)- or (−)-amphetamine respectively.

The variation in the excretion rate pattern of amphetamine was found not to be influenced significantly by changes in urine volume output, but rather appeared to be related to changes in urine *p*H (Fig. 1). A low urine *p*H resulted in a high excretion rate, whereas alkaline urine gave a low excretion rate. These results would appear to agree with the theory of non-ionic diffusion of bases in the distal portion of the kidney tubules[11,12]. The higher the urine *p*H, the higher will be the ratio of un-ionized amphetamine in the luminar fluid of the kidney tubules

relative to that in the plasma. This, in turn, will result in more drug being reabsorbed into the body and hence reduce the excretion rate of amphetamine.

Further trials in which the urine was kept acidic (pH 5·0 ± 0·2) by administering ammonium chloride showed that about 60 per cent of the drug was excreted unchanged over a 48-h period using a dose of 10 mg (+)-amphetamine sulphate. When the urine was kept alkaline (pH 8·0 ± 0·2) by the administration of sodium bicarbonate, only 5 per cent of the drug was eliminated over the same period. The fluctuations in the excretion rate of amphetamine were abolished by the control of urine pH at these relatively constant acidic and alkaline values.

It is known that diurnal changes in urinary pH occur[13–17] even under controlled conditions[18]; the rhythmic pattern of the amphetamine excretion rate under normal conditions is thus probably caused by this urinary pH rhythm.

PHARMACOLOGY

Effect of Altered Thyroid Status on Desmethylimipramine Mortality in Mice

In previous papers we have directed attention to the enhancement of imipramine mortality in mice by hyperthyroidism and its diminution by propylthiouracil pretreatment[1,2]. One of the major metabolites of imipramine is its demethylated product, desmethylimipramine (DMI)[3], and this compound is said to be responsible for the antidepressant effect of the drug[4,5]. DMI is more potent than imipramine in antagonizing reserpine sedation in rats[4] and in potentiating the reaction of cat nictitating membrane to norepinephrine[6]. For these reasons it seemed of interest to ascertain the effect of thyroid status on DMI mortality according to the previous technique.

Young (25–30 g) male Swiss–Webster white mice were given 0·2 per cent propylthiouracil in their drinking water for 30 days. At the end of this time they had gained less weight than controls, their coats were dingy, and they appeared somewhat sluggish. Work with other mice has shown that this treatment produces decreased oxygen utilization per unit body weight, and prolongs survival in closed jars. These mice were termed propylthiouracil-treated (PTU) rather than hypothyroid, since PTU is known to produce extra-thyroidal changes[7]. Another group of similar mice were fed 2 per cent desiccated thyroid in their food for 96 h. These mice were termed hyperthyroid (HR), as this treatment produces behavioural and metabolic changes characteristic of the disorder[1]. Control mice were treated in an identical way except that neither their food nor water was medicated.

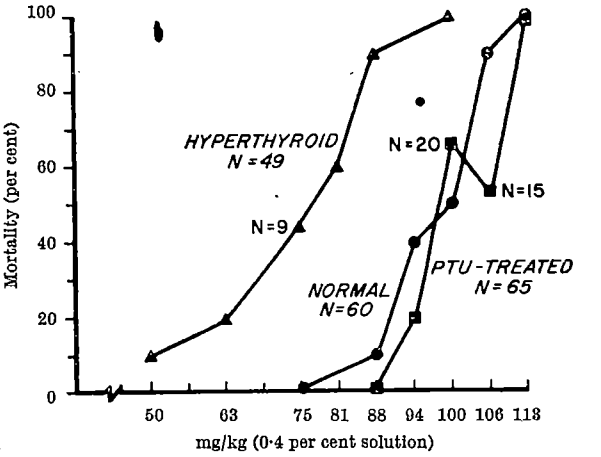

Fig. 1. Intraperitoneal desmethylimipramine acute (1 h) mortality in adult male Swiss-Webster white mice

On the same day in random sequence all mice were injected intraperitoneally with a 0·4 per cent saline solution of DMI. They were observed for 1 h, though the vast majority were dead or appeared to have recovered after 20 min. The mortality results are shown in Fig. 1.

DMI, like imipramine, shows enhanced mortality in HR mice though the magnitude of the effect is somewhat less. Increased rate of absorption from increased peritoneal vascularity in hyperthyroidism may partly account for this effect, but direct evidence is lacking. In any case, it is unlikely to be a sufficient explanation, since we have found that HR mice are more sensitive than controls to the mortal effects of pentobarbital, and also to sleep *longer* after a sub-lethal dose. Both imipramine and thyroid hormones interfere with the storage of administered norepinephrine, and their effects are additive[8], so that this, too, may account for the increased mortality in HR mice.

DMI mortality is not reduced by PTU. DMI is more potent than imipramine (LD_{50} = 100 mg/kg versus 115). It produces a steeper dose-mortality curve in all thyroid groups. It acts more quickly and its gross effects are dissipated more quickly. Mice given DMI appear stimulated and the occasional mouse may show opisthotonos, and even convulse, but the degree of stimulation is only a fraction of that seen after comparable doses of imipramine. These comments apply equally to all three experimental groups.

We were intrigued by the finding that PTU pretreatment spared imipramine-injected mice[2] but not DMI-injected mice. This finding, together with our other observations regarding rate of action and degree of stimulation, suggests that, while imipramine has stimulating properties of its own, DMI is the active metabolite, that demethylation occurs *in vivo*, and that PTU pretreatment interferes with the rate of demethylation, thus delaying the formation of the more potent DMI when mice are injected with imipramine.

To test the latter hypothesis, a group of mice were pretreated with PTU for 30 days and injected with an LD_{50} of either DMI or of imipramine. As expected, the pretreatment had no effect on DMI mortality rate. There was a tendency toward PTU sparing of imipramine-injected mice but this was statistically insignificant. Therefore, another group of mice were PTU treated for 60 days. Again the pretreatment had no effect on DMI mortality. The tendency toward sparing of imipramine-injected mice was slightly greater than at 30 days but still not statistically significant. Fourteen of 24 control mice died; 11 of 25 PTU mice. As in previous experiments the PTU sur-

vivors seemed to recover and to resume their usual habits more promptly than control survivors.

We have been unable to replicate to our satisfaction a PTU sparing effect on imipramine-injected mice. There is no evidence for such an effect in the case of DMI. More refined studies are in progress to determine whether PTU interferes with *in vivo* demethylation of imipramine. Both DMI and imipramine show enhanced lethal effects in HR mice. DMI is more potent, acts more quickly, and yields steeper dose-mortality curves than its methylated parent compound.

This work was supported in part by 325–*NIH*–290 (A. J. P.), and 325–*NIH*–304 (M. A. L.). Geigy, Inc., kindly furnished imipramine and DMI; and Lederle, Inc., supplied PTU.

Salicylate, a Powerful Inhibitor of Free Fatty Acid Release

THE level of utilizable glucose represents a control of the release of free fatty acids (FFA) and, therefore, of the level of serum FFA[1]. Drugs acting on glucose utilization are therefore likely to be effective in changing the level of FFA. The observation that salicylate increases oxidative reactions[2,3] led us to the finding that this drug is a powerful inhibitor of FFA release. Previous investigations carried out in man were contradictory. While Carlson[4,5] found a decrease of plasma FFA in normal and diabetic subjects, Gilgore *et al.*[6] did not confirm these results. However, it is likely that in the latter data there was an interference of salicylate in the determinations of FFA carried out according to Dole's method.

Male Sprague–Dawley rats of the average weight of 150 g were used for all experiments. Sodium salicylate was given intraperitoneally in resting animals as well as in animals submitted to treatments designed to increase the level of FFA.

FFA were determined according to the method of Trout[8] to avoid interference of salicylic acid with the titration. The inhibitory effect of salicylate is very clear in suckling, adult or adrenalectomized animals and in rats with an increased level of FFA induced by fasting, cold, noradrenaline, ACTH or chlorpromazine. The blockade of thyroid activity did not affect the inhibition exerted by salicylate.

Table 1

Treatment or experimental condition	FFA μequiv./1,000 ml. plasma	
	Controls	Salicylate 300 mg/kg i.p.
Saline	215 ± 21	137 ± 6
Fasting 18 h*	671 ± 64	341 ± 11
Cold, 2° C 4 h*	765 ± 60	111 ± 3
Norepinephrine s.c. 1 mg/kg †	723 ± 54	252 ± 36
ACTH 20 units* ¶	957 ± 37	201 ± 22
Chlorpromazine, i.v. 1,5 mg/kg‡	505 ± 22	138 ± 29
Adrenalectomy*	380 ± 60	143 ± 22
Suckling rats*	540 ± 77	308 ± 40
Suckling rats on propylthiouracil diet§	648 ± 36	326 ± 20

* Salicylate given 30 min before rat killed.
† Norepinephrine given in oil suspension; both drugs administered at the same time. Time between treatment and killing 60 min.
‡ Salicylate given 10 min before chlorpromazine injection. Rats killed 30 min after chlorpromazine injection.
§ Propylthiouracil 0·4 per cent in the diet given to the mothers (ref. 7) during 17 days before salicylate administration.
¶ ACTH was given 120 min before rat killed.

By using the test of the increased level of FFA after cold it was observed that quite small amounts (25 mg/kg) of salicylate exerted an effect, and the effect of a large dose (300 mg/kg) lasted about 2 h. Orally administered salicylate was also effective in a dose of 50 or 100 mg/kg. Acetylsalicylic acid and benzoic acid shared the effect of salicylate, while *p*-aminosalicylic acid and salicylamide were ineffective up to a dose of 300 mg/kg.

Preliminary experiments show that salicylate may act directly on the adipose tissue because it slightly inhibits the release of FFA by the epididymal fat pad *in vitro*. Large doses are necessary, however, so it cannot yet be said that there is a causal relationship between the inhibition of FFA release *in vitro* and the decrease of plasma FFA *in vivo*.

The effect of salicylate on the FFA is obtained without significant changes of blood glucose, but this should not be considered to contradict the hypothesis previously mentioned because a small increase in glucose oxidation would not necessarily be reflected in the level of blood glucose.

These results are relevant to the interpretation of the reported hypoglycæmic and hypocholesteræmic effects of salicylate[3].

Effect of Drugs on the Amount of Substance P in Rabbit Brain

THE content of 'Substance P' (SP) in the central nervous system under the influence of drugs has been studied repeatedly. Paasonen and Vogt[1] did not find an influence of D,L-amphetamine, ephedrine, insulin, caffeine, β-tetrahydronaphthylamine, and reserpine on the SP content of the hypothalamus and nucleus caudatus of anæsthetized dogs. Zetler and Ohnesorge[2] estimated the SP content of mouse brain after treatment with various centrally-acting substances, and found that substances which are centrally exciting in mice (benzedrine and morphine) increased the total content of SP in the brain, whereas chloroform, urethane and phenobarbital lowered it. Stern and Kocić-Mitrović[3] found an increase in SP content in rabbit brain after treatment with reserpine, but Laszlo[4] did not find any striking change of SP content in rabbit brain after reserpine and numerous other drugs.

The present experiments were made in order to obtain further data, using the purification technique of Pernow[5] for SP. Whole rabbit brain except cerebellum was used. The brain was ground, and boiled in acidified distilled water. After precipitation with ammonium sulphate SP was adsorbed on aluminium oxide and eluted with distilled water as described in detail by Pernow[5], Euler[6] and Radmanović[7].

Bioassay was performed on the isolated guinea-pig ileum with addition of atropine, promethazine and

d-lysergic acid diethylamide (LSD). All drugs were given to rabbits subcutaneously once a day for 3 days. Drugs used were : physostigmine salicylate (4 mg/kg), reserpine 'Serpasil-Ciba' (0·5 mg/kg), chlorpromazine chloride 'Hibernal-Leo' (5 mg/kg) and *p*-hydroxy mercuribenzoate (10 mg/kg).

The results are shown in Table 1. Only physostigmine salicylate had an effect on SP content in rabbit's brain. After 3 days administration of this drug concentration of SP in rabbit's brain decreased from 19 ± 1·5 u./g to 7 ± 0·73 u./g. The other drugs administered to the rabbits did not influence change of SP content in the brain.

Table 1. Amount of SP u./g in the Rabbit's Brain after Administration of Drugs

Drug	No. experiments	SP (u./g)	Significance
Control	5	19 ± 1·5	
Physostigmine salicylate	5	7 ± 0·73	$P < 0·01$
Reserpine	5	16 ± 1·3	Not sign.
Chlorpromazine	5	19 ± 2·1	,,
p-Hydroxy mercuribenzoate	5	16 ± 1·6	,,

These results are in accordance with those obtained from rabbit small intestine the SP content of which was also influenced only by physostigmine[7]. Similar results were obtained with reserpine and chlorpromazine by Paasonen and Vogt[1] and by Laszlo[4]. One possible explanation for the disagreement with results of other authors is the interference produced by nucleotides present in the SP extracts if they are not purified[4].

The physostigmine effect on SP content in rabbit brain, in conjunction with previous results[7], suggests a relation between central cholinergic mechanisms and SP.

Postnatal Behavioural Effects of Meprobamate injected into the Gravid Rat

Werboff and Kesner[1] have claimed that administration of meprobamate to gravid rats for four successive days during any period of pregnancy resulted in offspring that, compared with the controls, were lighter in body-weight and significantly poorer at learning a Lashley III maze. The latter deficiency was attributed to some unspecified effect of the drug on the developing brain. Since previous experience with meprobamate had not revealed any deleterious effects on body-weight or size among the progeny of meprobamate-treated females[2], and since it seemed unlikely that a cerebral impairment due to prenatal drug exposure should be unrelated to the embryo's age at the time of insult[3], we repeated the Werboff and Kesner experiment. This replication also provided the opportunity for verifying an earlier report by Werboff and Havlena[4] that prenatal exposure to meprobamate altered performance on the inclined plane and in the open-field test.

The experiments were carried out exactly as described by Werboff *et al.*[1,4]. Pregnant female rats were injected three times a day at approximately 8-h intervals for four days. One group received distilled water subcutaneously, the other group received meprobamate, 20 mg/kg dissolved in distilled water. They were injected during gestation on days 5–9, 10–14 or 14–18. The offspring were weighed twice-weekly. At 25 days of age they were given three trials on an inclined wire screen, but no more than 120 sec were allowed per trial. The shortest time required to reach the top was selected for calculating the time of climbing. At about 55 days of age the rats were placed in the open field (a 5-ft. × 3-ft. grid of 12-in. squares) for 120 sec once a day for five consecutive days. The number of squares crossed and the activities (number of fæcal boli, etc.) were counted. At 75 days of age the rats were placed on a 23-h food deprivation schedule and began seven days of preliminary training on a 36-in. straight alley. On the eighth day of training, practice on the Lashley III maze was started with the following schedule: days 8, 9, 10—2 trials per day; days 11, 12, 13—3 trials per day; days 14, 15—5 trials per day. The criterion of learning was two out of three correct trials run in 20 sec or less per trial.

No measure revealed any significant difference between the offspring of meprobamate-treated and those of water-treated rats. Body-weights at 75 days of age, for example, averaged 288·3 ± 38·6 g for control males as compared with 290·4 ± 36·7 g for experimental males, while female offspring weighed 186·2 ± 22·4 g and 190·1 ± 36·0 g for control and experimental groups, respectively. Median inclined plane scores were 13·5 (range 2–120) sec for control and 16·5 (range 2–120) sec for animals of the experimental groups. The difference was not statistically significant at the 0·05 level. Furthermore, open-field scores were not significant for the number of squares traversed nor was emotionality significantly different between the two groups at the 0·05 level. There was no significant difference between the drug-tested animals and the controls in learning the Lashley III maze (Table 1). The learning scores of the offspring were also analysed according to the stages of pregnancy during which their mothers had been injected. No significant differences were found relating either to the substance injected or to the fœtal age at which injections were made.

Table 1. Trials to Criterion on Lashley III Maze of Progeny of Rats Administered Meprobamate during Various Stages of Pregnancy

Group	No. rats	Total stages	Stage First (3–9 days)	Second (8–12 days)	Third (13–18 days)
			(Mean number of trials ± *S.E.*)		
Control	81	14·2 ± 0·6	14·5 ± 1·2	12·9 ± 2·3	14·2 ± 0·7
Meprobamate	83	12·8 ± 0·6	15·0 ± 3·6	13·0 ± 0·8	12·1 ± 0·9

Our experiments have failed to verify the reports by Werboff *et al.*[1,4] of behavioural alterations subsequent to prenatal exposure to meprobamate. Furthermore, neither these rats nor those previously described by Berger have shown the weight loss which was noted in Werboff's rats and attributed by him to meprobamate. It appears likely that the behavioural data presented by Werboff are merely a reflexion of the poor physical status of his rats. Our results clearly show that the physical status of the offspring of meprobamate-treated rats should be in no way inferior to the offspring of the untreated animals. Treatment with meprobamate during *pregnancy* did not cause any impairment of performance on an inclined plane, behaviour in the open-field test, or in ability to learn a maze by the offspring.

HÆMATOLOGY

Abnormal Transport of Vitamin B_{12} in Plasma in Chronic Myelogenous Leukæmia

RECENTLY[1] we demonstrated that two substances which we believe to be proteins carry the vitamin B_{12} in the plasma of normal subjects. These will be referred to as transcobalamin I and II. We then investigated their behaviour in the plasma of patients with chronic myelogenous leukæmia (CML) and found a major abnormality.

In the investigation of the control subject and of those with leukæmia, plasma which was taken at various times after intake of $^{57}CoB_{12}$ was fractionated by DEAE-cellulose anion-exchange column chromatography. Normally[1], almost all of the $^{57}CoB_{12}$ as it is taken into the plasma from injection, or from the intestine, is bound to a protein which was eluted pre-albumin, transcobalamin II. The B_{12} is rapidly lost from this binding site and little remains after the first day. A small amount of the B_{12} recently taken into the body and all the endogenous B_{12} which has been present in plasma for some time is bound to an alpha-1 globulin, transcobalamin I, the first binding substance to be described[2,3]. The loss from this binding site is quite slow.

When a patient with chronic myelogenous leukæmia was given 0·8 μg of $^{57}CoB_{12}$ by mouth, almost all the radioactive B_{12} was taken up by transcobalamin I, a complete reversal of the normal pattern. The plasma peak was not reached until 24 h in contrast to a peak at 8 h in normal subjects. There was little loss from this binding site during the next 24 h, and more than 50 per cent remained at 13 days. Two other subjects with CML were given 1·0 μg intravenously. Here, too (Fig. 1), almost all the $^{57}CoB_{12}$ was bound to transcobalamin I. In a normal subject almost all would have been bound to transcobalamin II. The investigation was repeated 3½ months later when the patient was in a good remission induced by 'Busulfan'. As shown in Fig. 2, transcobalamin II participated to a much greater extent than previously, an apparent return towards the normal. Usually we have found a sharp peak of $^{57}CoB_{12}$ in the transcobalamin II region, and while the peak in this case was in the expected position, it was unusually broad. The *in vitro* binding of 300 μμg/ml. of plasma was examined in 4 patients with CML in relapse. An abnormal binding pattern was found which was identical to that found when the $^{57}CoB_{12}$ was added *in vivo*.

The abnormality of the binding of B_{12} in the plasma in CML could be due to an increase in transcobalamin I, to a decrease in transcobalamin II, to a change which alters the binding capacity of either, or to some chemical change in the plasma which alters the union of B_{12} and transcobalamins which carry it. Because they give up their B_{12} at very different rates, the two transcobalamins appear to have different functions. The abnormality of plasma transport of B_{12} in CML could therefore alter the distribution of B_{12} within the body.

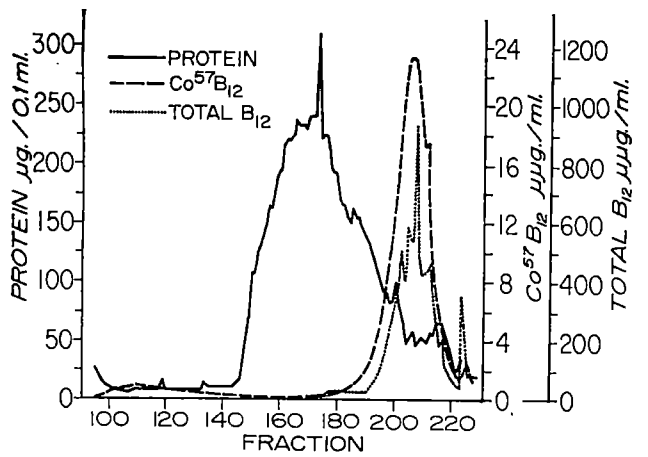

Fig. 1. Fractionation of plasma taken 1·5 min after i.v. $^{57}CoB_{12}$ from a subject with chronic myelogenous leukæmia in relapse. Total B_{12} includes both endogenous and recently injected B_{12}. Both are bound to transcobalamin I (peak in fractions 207–208) with only a trace of $^{57}CoB_{12}$ in transcobalamin II (peak in fraction 109). Fractions 0–95 contained γ and β globulin but no B_{12}

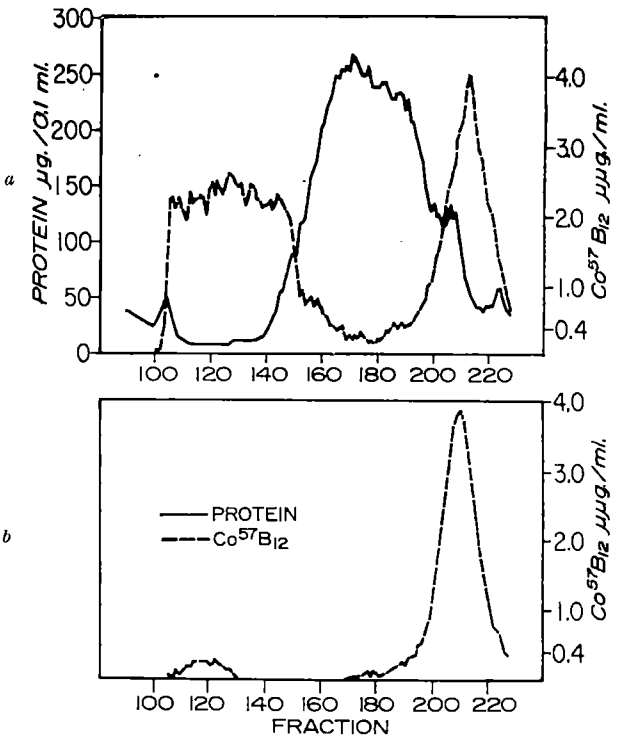

Fig. 2. A study of the same patient as Fig. 1 during remission. Note the rapid loss from transcobalamin II and the slow loss from I. (*a*) Plasma taken 1·5 min after injection, (*b*) plasma taken 90 min after injection

In vivo Maturation of Immature Reticulocytes transfused into a Normal Rabbit

WE have recently published the results of an investigation of polyribosomes and the loss of synthesis of hæmoglobin in maturing rabbit reticulocytes fractionated by buoyant density centrifugation in an albumin gradient[1]. Several cytological and biochemical criteria were applied to show that this procedure fractionates the reticulocyte population according to their degree of physiological maturity. This communication presents additional proof, using *in vivo* maturation of a fraction of the youngest reticulocytes, that the position of the cells in the albumin gradient is a function of their age. In addition, these investigations provide an estimate of the life-span of the reticulocytes produced in phenylhydrazine-induced anæmia.

Reticulocyte fractionation by buoyant density centrifugation in bovine serum albumin (BSA) gradients and *in*

vitro incubations were performed as previously described[1]: 1·75 ml. of the most immature cells were isolated from 9·7 ml. of reticulocytes from a phenylhydrazine anæmic rabbit and incubated in the complete reaction mixture with 2 mc. of L-leucine-4,5-^{3}H, 3·37 mc./μmole (Nuclear Chicago), for 1 h at 37° C. These tritium-labelled cells were washed, suspended in 2 vol. of rabbit serum containing 5 mg/ml. sodium citrate and injected into the marginal ear vein of a normal rabbit. Blood samples of 10 ml. each were taken from the ear of the recipient after 1 h and at various intervals thereafter for 15 days (Fig. 1). After measuring blood and cell volumes, the cells were washed in NKM and suspended in 0·5 vol. of NKM. Five to six ml. of this cell suspension were fractionated on a 25-ml. BSA gradient, and collected in 1-ml. fractions. Cells from each fraction were washed with NKM and lysed with 0·8–1·6 ml. of lysing solution[1]. Stroma pellets were washed with 0·2–0·4 ml. of 0·1 M KCl, 0·1 M *tris*, *p*H 7·5, and the washings added to the stroma-free lysate.

Radioactive protein was determined by treating 0·1–0·5 ml. of lysate with 5 ml. of 1 per cent HCl in acetone to remove the hæm. The protein precipitate was centrifuged, washed with acetone, dried, and dissolved in 3 ml. water. One-tenth-ml. aliquots of these final protein solutions were added to 10 ml. of Bray's solution[2] for liquid scintillation counting.

The distribution of radioactivity in the blood samples analysed on BSA gradients is shown in Fig. 1. The time of sampling, given in hours after the initial injection of labelled cells, is indicated for each curve. In the first sample, taken 1 h after injection, the labelled cells reband at almost the same position as on the original gradient from which they were isolated. In the blood samples taken during the first two days following injection, the tritiated cells banded in successively lower (denser) positions in the gradient as they matured *in vivo*. During this time the position of the peak of radioactivity on the gradients moved linearly with time toward more dense fractions (Fig. 2). A similar but slower increase in density with age has been observed in normal rabbit erythrocytes by Leif and Vinograd[3]. The results presented here confirm our earlier report based on cytological and biochemical evidence that the position of the cells in the gradient is a function of their age.

After the first two days, the banding position of the tritiated cells rapidly levels off two-thirds of the way down the gradient at fraction 9. This final banding position corresponds in density to that of the lightest normal erythrocytes. We have previously shown that the least dense cell fractions consist of the most immature, macrocytic reticulocytes[1]. The present findings show that such cells mature to erythrocytes which are less dense than the majority of normal erythrocytes. This maturation, in terms of buoyant density changes, occurs in about 48 h. Since the injected reticulocytes band well above the normal erythrocytes during the first day, this method offers the possibility of studying the biochemical events of maturation *in vivo*. Such studies have been precluded in

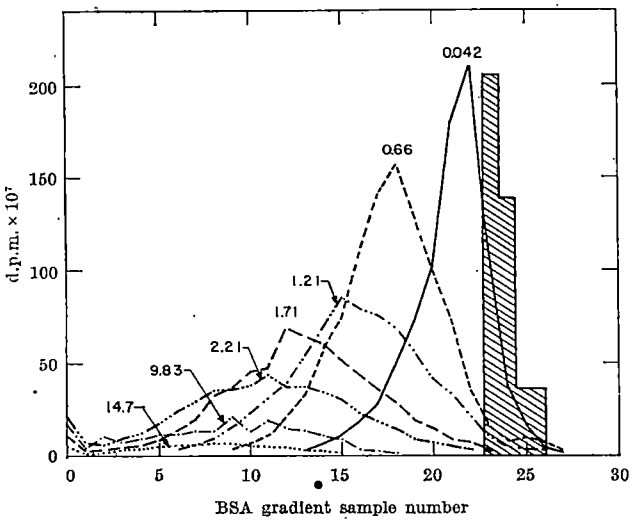

Fig. 1. Distribution of radioactivity in the blood cell samples as analysed on BSA gradients. Time, in days, after injection of tritium-labelled reticulocytes is indicated for each curve. Gradient samples are numbered from the densest (1·090 g cm^{-3}, 24° C) to the lightest (1·065 g cm^{-3}, 24° C). Cross-hatched area represents the position of the initial band of young reticulocytes as isolated from a phenylhydrazine anæmic rabbit

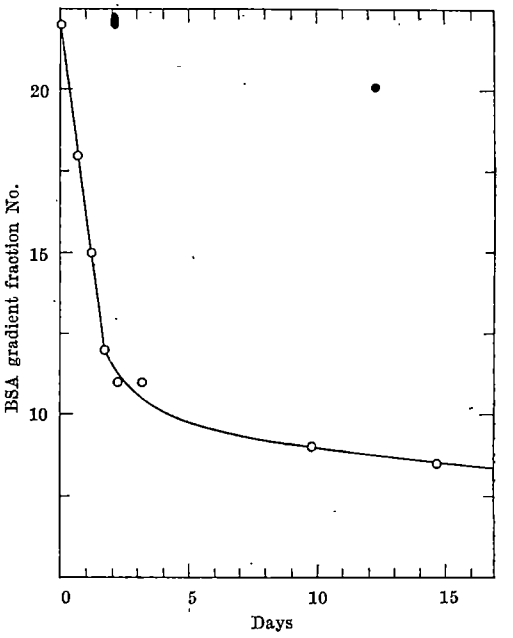

Fig. 2. Position of peak of radioactive cells as analysed on BSA gradients, as a function of time after transfusion

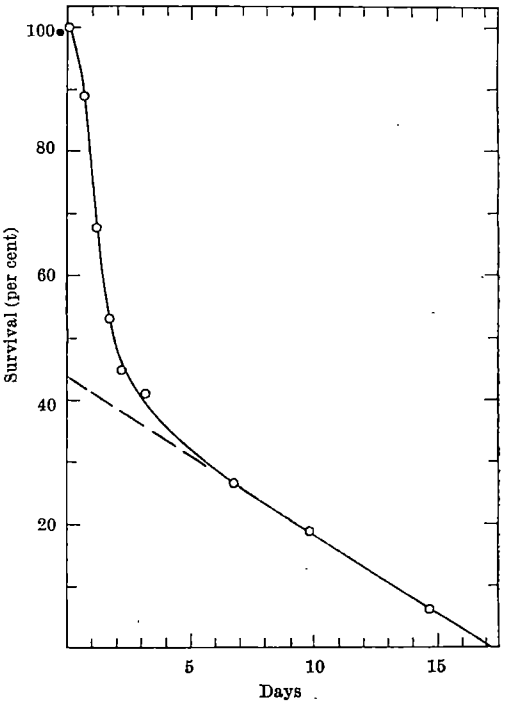

Fig. 3. Per cent survival of tritium-labelled reticulocytes as function of time after transfusion. Values represent per cent of initial radioactivity injected, corrected for cell samples removed

anæmic animals due to the constant influx of new reticulocytes from the bone marrow.

A graph of the per cent survival of the labelled cells versus time (Fig. 3) shows two distinct populations. One population, approximately 55 per cent of the injected cells, shows a life-span of about two days. The remaining 45 per cent of the cells disappear from the circulation after 17 days. A similar survival curve of sickle cells transfused into normal human beings has been reported by Singer and Fisher[4]. This is evidence for the extremely short life-time of the red blood cells which arise in response to a hæmolytic crisis. Previous reports, based on *in vivo* incorporation of ^{14}C-glycine[5] and incorporation of iron-59 (ref. 6), have indicated considerably long half-lives, of about 19 days, for such reticulocytes. However, the present findings are not only consistent with the results of *in vivo* ^{14}C-valine labelling of reticulocytes reported by Borsook *et al.*[7], but are in excellent agreement with the survival times observed by Mazur and Carleton for ^{14}C-glycine labelled reticulocytes transfused into normal recipients[8]. Such extremely short life-spans are not unexpected since survival times as short as four days have also been observed in several hæmolytic anæmias of human beings[9–11].

We thank Prof. Henry Borsook for his advice.

Chemical Reactivity of Avian and Mammalian Hæmoglobins of Different Ages

THE structural alteration of mammalian hæmoglobin on ageing *in vivo* is evidenced by the accelerated electrophoretic mobility of older hæmoglobin[1] and its changed chromatographic behaviour[2]. Hybridization investigations have shown the variant chain in old hæmoglobin to be the β-chain[3]. A number of suggestions have been made as to the possible chemical nature of the modification[4], the main one being that mixed disulphide formation with glutathione occurs[5,6] as a consequence of the diminished enzyme activities present in older red blood cells.

The development of methods for the separation of young and old mammalian red blood cells by centrifugation[7] or by counter-current distribution[8] or of their lysates by a serial osmotic hæmolysis procedure[9] has led to a probing of the enzymological and morphological differences of these cells and also to an examination of the relative reactivities of hæmoglobin as a function of its age. The latter investigations may possibly provide some information on the conformational differences between young and old hæmoglobin. Thus, Edwards *et al.*[10] reported that the dialysed macromolecular fractions derived from young and old erythrocytes have a different oxyhæmoglobin saturation; and Walter[11] found that young mammalian hæmoglobin binds more chromium-51 than its older counterpart. Since ^{51}Cr is known to be bound by the β-chain of mammalian hæmoglobin[12], the reported alterations in structure and chromium binding on hæmoglobin ageing occur on the same chain.

Although mammalian hæmoglobins show great structural similarities, as revealed by their peptide maps ('fingerprinting')[13], chicken hæmoglobin is completely different. Our interest, therefore, turned to an examination of the behaviour of young and old chicken hæmoglobins with respect to chromium binding.

We have recently reported that young and old chicken erythrocytes, like their mammalian counterparts, exhibit a correlation between their age and their resistance to hypotonic lysis[14]. It was further found that young and old chicken erythrocytes take up ^{51}Cr to the same extent. This finding differs from the preferential uptake of ^{51}Cr by young mammalian red blood cells[15]. In the latter case it was shown that the increased uptake of ^{51}Cr by young mammalian erythrocytes is due to the increased ^{51}Cr binding by young hæmoglobin[11]. This communication presents results showing that the equal labelling of young and old chicken erythrocytes with ^{51}Cr is due to the corresponding equal labelling of chicken hæmoglobin derived from these cells rather than to an alteration of red cell permeability to chromium as a function of age or to some other factor[15] unrelated to hæmoglobin structure or reactivity.

White Leghorn hens were injected intravenously via the wing vein with 50–75 μc. of ^{59}Fe in the form of ferrous citrate. The blood was collected one (chickens Nos. 20, 22, 23) or two (chicken No. 19) days later in acid–citrate–dextrose (ACD) solution. The red cells were washed five times at room temperature with isotonic saline, and the serial osmotic hæmolysis procedure of Simon and Topper[9] was used to obtain separately lysates enriched with respect to young or old cells. Lysates corresponding to younger cells have higher specific activities than those from older cells, enabling us to verify the age of cells giving rise to a particular lysate by measuring its specific activity (that is, the number of ^{59}Fe counts/min/absorbancy unit at 540 mμ). The hæmoglobin in the most concentrated lysate derived from the younger cells or of the older cells was purified by precipitating most of the non-hæmoglobin proteins by half saturation with neutralized ammonium sulphate. After removal of the precipitate, the hæmoglobin solution was made saturated with respect to ammonium sulphate, and the hæmoglobin was centrifuged off. The hæmoglobin was dissolved in water and dialysed. Solutions containing identical amounts of younger or older chicken hæmoglobin were diluted to equal volumes and the hæmoglobin labelled by standard methods with the same amount of ^{51}Cr (about 0·5 μc./absorbancy unit) and then treated with sodium ascorbate[16]. Hæmoglobin was precipitated by adding solid ammonium sulphate to the saturation point and allowed to stand in the cold overnight; it was centrifuged, dissolved in water and dialysed overnight. The specific activity of hæmoglobin with respect to ^{51}Cr was determined using a scintillation well-counter with a Baird-atomic pulse-height analyser and a spectrophotometer.

The results presented in Table 1 show that young and old chicken hæmoglobins take up ^{51}Cr at the same rate and to the same extent. This behaviour of chicken hæmoglobin thus differs from that of mammalian hæmoglobin where the younger hæmoglobin is found to take up appreciably more ^{51}Cr than the older hæmoglobin[11].

Although the internal environment of the chicken erythrocyte appears to change on ageing in a way similar to that observed in the mammalian red blood cell[14], this altered environment (that is, the diminution of enzyme activities on erythrocyte ageing) is obviously not all that is required for a structural alteration in hæmoglobin, detectable by a decrease in ^{51}Cr binding, to occur. The

PATHOLOGY

Uptake of Protein by Regenerating Liver Cells

Using an immunofluorescent method, Cohen and his colleagues[1] reported that hepatomas induced in rats by *p*-dimethylaminoazobenzene could take up plasma proteins without prior extracellular hydrolysis. Later we showed[2] that intact plasma proteins could similarly be demonstrated within the cells of benzpyrene-induced primary fibrosarcomas in rats, and several other transplanted mouse tumours, both in solid and in ascites forms. However, the question whether this capacity of taking up intact protein molecules is associated with malignancy or is a property of all rapidly growing tissues remained unanswered. The present investigation was designed to study the uptake of intact protein molecules in a rapidly growing tissue *in vivo*, namely in regenerating rat liver cells after partial hepatectomy.

Lister hooded rats (180–220 g) of either sex were partially hepatectomized—approximately half to two-thirds of the liver parenchyma was removed. Protein uptake was investigated both by direct fluorescent protein tracing and by the fluorescent antibody method. For direct tracing, normal human serum globulin was conjugated with lissamine rhodamine *B* (*RB* 200) and was injected into the jugular vein of rats. The dose injected was approximately 60 mg protein/200 g of body-weight. For the immunofluorescence method a γ-globulin fraction was injected in the same dose and by the same route.

Pairs of rats were killed 1, 2, 3, 6, 12, and 24 h after hepatectomy and then once every 24 h until the 20th day. Protein uptake was studied in one of the two rats by the immunofluorescent method and by direct fluorescent protein tracing method in the other. After the 20th day only one rat was killed daily until the 35th day, and protein uptake was studied by immunofluorescent and direct fluorescent protein tracing methods on alternate days. Some parts of this serial study were repeated and protein uptake was investigated in about 150 hepatectomized rats. The rats received the appropriate proteins intravenously at least 1 h before death. Small blocks of liver tissue were snap-frozen immediately after killing and were then sectioned at 5μ in a cryostat. In the direct tracing experiments, the sections were fixed in 95 per cent ethanol for 30 sec, and were then rinsed in phosphate-buffered saline (*p*H 7·1) and mounted in buffered glycerol. In the immunofluorescence experiments, the unlabelled human γ-globulin was identified in ethanol-fixed sections, after treating for 30 min with goat anti-human-γ-globulin conjugated with *RB* 200. Liver from normal and hepatectomized rats not injected with proteins served as controls. The specificity of immunofluorescent staining was assessed by treating parallel sections with labelled anti-rabbit-globulin which, of course, failed to stain.

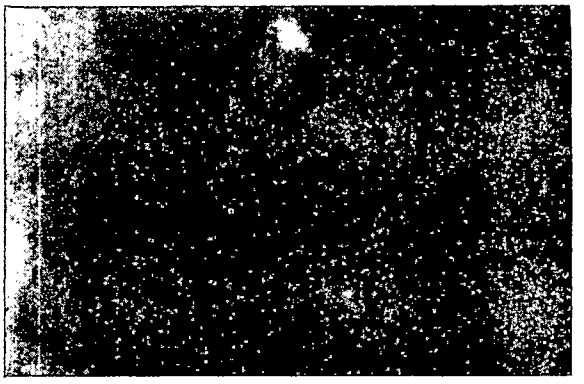

Fig. 1. Frozen section of a rat liver on the sixth day after hepatectomy. The liver was removed 2 h after intravenous injection of human serum globulin conjugated with *RB* 200. The fluorescent protein aggregates can be distinguished as droplets in the cytoplasm of the hepatic cells

Examination of preparations with the fluorescence microscope showed distinct fluorescent protein aggregates in hepatic cells by the end of the fifth day: very small amounts were perhaps present in the hepatic cells on the second, third and fourth days but the appearance was not conclusive. Between the fifth and tenth days after hepatectomy uptake was maximal; afterwards it gradually fell, and virtually no protein could be demonstrated within hepatic cells after the fourth week of hepatectomy.

The proteins were distributed as droplets within the cytoplasm of the occasional single hepatic cell or in small groups of cells (Fig. 1), and these positive cells were found near the line of section as well as far removed from it. In the days immediately after hepatectomy a few necrotic areas could be seen near the line of section, and these showed an intense green autofluorescence, although no *RB* 200 orange fluorescence could be demonstrated. Küpffer cells always took up protein in normal[2] as well as in regenerating livers, but they can be easily distinguished from the hepatic parenchymal cells.

Regenerating hepatic tissue *in vivo*, therefore, shares with malignant cells the capacity to take up intact protein molecules. It has to be remembered, however, that hepatic parenchymal cells, even after minor injury, are known to be permeable to serum proteins[3], and further studies must be made on other rapidly growing *in-vivo* systems before any generalization can be made. Moreover, we have yet to learn whether the uptake of intact protein molecules is attributable to increased permeability of the cell membranes of rapidly growing tissues or to a more active process, and also how such intracellular serum proteins contribute to the increased metabolic demands of rapidly growing systems.

Existence in the Thymus of a Factor protecting the Skin of the Mouse against the Induction of Skin Cancers induced by 20-Methylcholanthrene

MILLER[1] has shown that thymectomy in the neonatal period of life favours the development of skin benzpyrene cancer in mice.

Vandeputte and De Somer[2] have shown that rats thymectomized during the first days after birth are still susceptible to the induction of cancers by polyoma virus during several weeks after birth.

We have shown[3] that subcutaneous isologous grafts of neonatal thymus repeated every 14 days protect the mice, to a certain extent, against the induction of cancer by 20-methylcholanthrene. Furthermore, we have shown that repeated injections of homogenized neonatal thymus also protect the mice against the same type of cancer, suggesting the possibility of the existence in the thymus of an extracellular factor or factors protecting the skin of the mouse against induced cancer. However, the existence of such factor or factors has not been demonstrated in this last experiment[4].

Therefore, we have undertaken another experiment in order to investigate the possible existence of such a factor or factors in neonatal thymus of the mouse. We have selected 3 groups of 60 mice of the same age and the same sex (50 per cent of each sex in each group) belonging to an isologous strain, the *L* strain of the Cancer Institute of Louvain. One group has been kept as control and painted 3 times a week with two drops of a 1/400 20-methylcholanthrene solution in ether, up to a total of 23 paintings. The two other groups have been painted similarly, but in addition have been injected every 14 days with thymus extracts, prepared as follows : every week, during the whole course of the painting period, 60 neonatal thymuses from young mice, aged 2–5 days, have been thoroughly homogenized in a Potter tube and then suspended in normal saline. This suspension has then been centrifuged for 30 min at a speed of 40,000 r.p.m. The supernatant, after this centrifugation, has been injected to the second group of our experimental animals. The sediment has then been re-suspended in normal saline and injected to the third group of our animals. Each animal of those two groups received thus every 14 days the corresponding amount of more or less one neonatal thymus, either in the form of the sediment or as supernatant. After the painting period the same injections were repeated every 14 days until the end of the experiment. There is no doubt that the supernatant represents an extract of thymus in normal saline devoid of cells. The results of the experiments are presented in Table 1.

Table 1

	No. of animals alive after 60 days	No. of tumours after (days) 60	90	120	150	180*	No. of animals alive at 180 days	No. of animals without tumour at 180 days†
Controls	63	2	7	20	24	32	23	7
Supernatant	58	4	4	6	10	15	33	21
Sediment	39	1	2	2	6	10	21	7

* $\chi^2_{1a} = 6.89$ $(1/2)P < 0.01 = P < 0.005$
$\chi^2_{1b} = 5.29$ $(1/2)P < 0.05 = P < 0.025$
† $\chi^2_{1a} = 4.72$ $(1/2)P < 0.05 = P < 0.025$
$\chi^2_{1b} = 0.015$ $(1/2)P < 0.70 = P < 0.35$

The differences between the results of the three groups are marked. Both groups injected with thymus show, during the whole course of the experiment, a marked delay in the development of cancer. At the end of the period of observation (180 days), there is still a marked difference in cancer incidence among the three groups. Moreover, the number of animals surviving at the end of the experiment without tumours, benign or malignant, is markedly higher in the group injected with the thymus supernatant. On the other hand, there is no marked difference in cancer incidence between the group injected with the supernatant and the group injected with the sediment after centrifugation. This, obviously, shows that only part of the active factor or factors, soluble in normal saline, has been extracted through this fractionation and that an important fraction of those factors remains in the sediment. We know nothing yet about the chemical nature of this factor or factors. We do not know either if the factor or factors are heat-resistant or not. Nor do we know if a heterologous extract of thymus would be active.

From the results of this experiment, it may be concluded that there exists, in the neonatal thymus of the mouse of strain *L*, a factor or a group of factors soluble in normal saline protecting the skin of the mouse of the same strain against the incidence of cancers induced by 20-methylcholanthrene.

Blastomyces (Paracoccidioides) brasiliensis in Africa

SINCE the discovery of "South American Blastomycosis" by Adolfo Lutz in 1908, it has been generally accepted that the disease is confined to South America. The few cases reported outside this region are of patients who lived for years in South American countries and probably contracted the "Lutz disease" there[1–8].

A sample of spinal fluid taken from a four-year-old Ghanaian girl living in Accra was sent to my laboratory. The clinical diagnosis was miliary tuberculosis. A few hours later the child died. Specimens of heart and liver tissue were taken. The spinal fluid was clear and apparently normal. The fragments of heart and liver tissue were covered with miliary abscesses. After centrifugation the spinal fluid was examined by routine procedures in dry and wet mount preparations. Spheres with refractile walls ranging from 5 to 30μ diameter were seen. In indian ink preparations no capsules were found. The heart tissue was ground with saline and the liquid phase was examined in wet mount preparations. In addition to the

spheres described above, large spheres ranging from 10 to 30μ appeared covered with small buds. These multiple budding cells strongly suggest the tissue forms of *B. brasiliensis*. Histological sections from post-mortem material revealed single and multiple budding spheres stained deep red by periodic acid–Schiff.

The liquid phase extracted from heart tissue was inoculated in Sabouraud glucose agar and in nutrient broth-serum agar. In Sabouraud glucose agar, growth is extremely slow and no fully developed colony has yet been obtained.

The liquid phase extracted from heart tissue was mixed with antibiotics and inoculated intra-peritoneally in mice (strain 'N.I.H.', U.S.A.). Four weeks later the animals, all in apparently good health, were killed. No macroscopic lesions were visible. In histological sections there were no noticeable lesions.

However, in histological section stained by the periodic acid–Schiff stain, multiple-budding cells like those seen in the patient's tissues were seen.

The diagnosis of *B. brasiliensis* in this case is based on: (*a*) The presence of multiple budding cells in the liquid phase extracted from heart tissue. (*b*) The presence of multiple, budding, mulberry-like cells stained deep red by periodic acid–Schiff in the patient's tissues.

From the evidence it appears that I have found a case of 'South American Blastomycosis' which must have been contracted in Africa. This case is unique so far as I know and unfortunately has not been fully documented. I have practically no clinical observation and no information on the environmental conditions in which the disease developed. The case cannot be evaluated properly until others have been described.

I thank Prof. C. da Silva Lacaz for his interest and advice, Prof. J. Gilman for facilities, and Drs. G. Lythcott and J. Edgecomb for the collection and preparation of material.

Role of Bradykinin in the Development of Acute Pancreatitis

The ability of bradykinin or kallidin to cause hypotension, pain, vasodilatation, increased vascular permeability, smooth muscle stimulation, leucocyte migration, and leucocyte accumulation suggests the possibility that bradykinin may play a part in a disease process, such as acute hæmorrhagic pancreatitis, characterized by hypotension, pain, hæmoconcentration, dynamic fluid shifts with the accumulation of ascitic fluid, leucocytosis, and œdema and leucocytic infiltration of the gland[1,2]. The attractiveness of this hypothesis is enhanced by the knowledge that the pancreas contains large quantities of trypsinogen and kallikreinogen, both of which, in active form, are capable of releasing bradykinin from its inactive precursor, bradykininogen. Bradykininogen, as a normal pseudoglobulin of plasma, lymph, and interstitial fluid, is readily available to the pancreas[1].

This tempting circumstantial evidence notwithstanding, attempts at demonstrating a role of bradykinin or kallidin in the pathogenesis of acute pancreatitis have been inconclusive[3]. No small part of the frustration has been the problem of obtaining a quantitative measurement of the active bradykinin of the body fluids[4]. However, a reliable method for the measurement of the bradykinin precursor, bradykininogen, has been described[5]. By determining the disappearance of precursor over time, one can estimate the bradykinin release. In work recorded here, because of the dynamic fluid shifts and colloid concentration that occur in severe acute pancreatitis, values for bradykininogen in weight per unit volume were corrected to weight per total plasma volume. The latter value was termed 'total circulating bradykininogen'.

Adult dogs of either sex were splenectomized two weeks before experiment. The animals were anæsthetized with sodium pentobarbital, 30 mg/kg. Pancreatitis was induced by a modification of the method of Elliott[6,7]. The animals were divided into three groups: Group 1, laparotomy only; Group 2, laparotomy followed by the induction of pancreatitis; Group 3, laparotomy followed by the intravenous injection of 'Trasylol', 25,000 units, followed by the induction of pancreatitis. 'Trasylol' was administered to the last group as a potent trypsin-kallikrein inhibitor capable of inhibiting the release of bradykinin-like polypeptides[8].

Mean femoral arterial pressure was monitored continuously. Blood samples were taken through a polyethylene cannula inserted into a femoral vein with the cannula tip advanced into the right atrium. Blood was collected in siliconed glassware and anticoagulated with balanced oxalate, 2 mg/ml. A control blood volume measurement was obtained and determinations were repeated once-hourly for 5 h. Hæmatocrits were determined at each blood volume measurement. At the end of each experiment (4 h after the induction of pancreatitis) the animal was killed, the volume of the peritoneal fluid was measured, and an estimation was made on the increase in size of the pancreas.

All animals of Groups 2 and 3 developed an acute hæmorrhagic pancreatitis. The mean arterial blood pressures of these animals dropped below 80 mm mercury within 3–14 min after the induction of pancreatitis. Three animals of Group 3 showed return of mean arterial pressure above 90 mm mercury. The pancreas became swollen, developed areas of interstitial hæmorrhage, and could be seen to exude a dark red fluid, containing fat droplets, within 15 min of the onset of pancreatitis.

Table 1

Parameter	Group 1 (3 animals)	Group 2 (5 animals)	Group 3 (6 animals)	*P* (<)
Blood volume loss (%)	3·77 ± 3·53	22·84 ± 2·00		0·01
	3·77 ± 3·53		16·18 ± 0·55	0·01
		22·84 ± 2·00	16·18 ± 0·55	0·02
Plasma volume loss (%)	5·17 ± 3·20	31·52 ± 3·98		0·01
	5·17 ± 3·20		26·00 ± 2·90	0·002
		31·52 ± 3·98	26·00 ± 2·90	> 0·10
Red cell mass loss (%)	3·90 ± 2·41	11·1 ± 2·60		> 0·05
	3·90 ± 2·41		4·12 ± 2·07	> 0·10
		11·1 ± 2·60	4·12 ± 2·07	> 0·05
Hæmatocrit	0·00 ± 0·56	7·20 ± 1·66		0·01
	0·00 ± 0·56		6·83 ± 1·54	0·01
		7·20 ± 1·66	6·83 ± 1·54	> 0·10

Group values include ± *S.E.M.*
'Per cent loss' and 'change' parameters denote differences between control measurements and the terminal measurements, four hours after the onset of pancreatitis.

Table 1 demonstrates the profound fluid shifts that occur in acute pancreatitis. Almost all the measured blood volume losses could be accounted for by the fluid found in the peritoneal cavity plus the gain in volume of the pancreas itself.

The total circulating bradykininogen loss, percentage change of the total circulating bradykininogen, and the calculated bradykinin release are seen in Table 2. No significant change in bradykininogen concentration (μg/ml. plasma) was evident during the period of observation.

A role of bradykinin in the pathogenesis of acute pancreatitis is probable in view of the following findings.

Table 2

Parameter	Group 1 (3 animals)	Group 2 (5 animals)	Group 3 (6 animals)	P (<)
Total circulating bradykininogen loss (mg)	0·097 ± 0·055	0·683 ± 0·130	0·385 ± 0·067	0·01
	0·097 ± 0·055		0·385 ± 0·067	0·02
		0·683 ± 0·130	0·385 ± 0·067	> 0·05
Total circulating bradykininogen loss (%)	8·30 ± 4·58	47·12 ± 6·65		0·01
	8·30 ± 4·58		24·55 ± 2·59	0·001
		47·12 ± 6·65	24·55 ± 2·59	0·02
Bradykinin release (μg/kg)	9·20 ± 4·74	73·14 ± 12·57		0·01
	9·20 ± 4·74		39·32 ± 7·36	0·02
		73·14 ± 12·57	39·32 ± 7·36	0·05

Group values include ± the *S.E.M.*

Among the animals of Group 2, the calculated bradykinin release was of sufficient magnitude to account for sustained hypotension. Bradykinin release was seen to correlate with severity of disease as manifest by hæmatocrit change ($r = 0{\cdot}719$, $P < 0{\cdot}01$) and peritoneal fluid accumulation ml./kg ($r = 0{\cdot}812$, $P < 0{\cdot}001$).

'Trasylol' given immediately before the onset of pancreatitis resulted in amelioration of the disease experienced by those animals composing Group 3. The amelioration was evident in terms of duration of hypotension, per cent blood volume loss, per cent total bradykininogen loss, and bradykinin release. The ability of 'Trasylol', an agent capable of inhibiting bradykinin release, to lessen the severity of pancreatitis buttresses the hypothesis that bradykinin is active in the development of acute pancreatitis.

This investigation was supported by FBA Pharmaceuticals, Canada, which also made a gift of 'Trasylol'. Synthetic bradykinin was the gift of Dr. K. Royal Stewart, Sandoz Pharmaceuticals, Canada.

IMMUNOLOGY

Strain Immunity in Babesiosis

The importance of immunological differences between strains in the epidemiology of human malaria is well known[1]. A disease comparable in some respects with malaria is bovine babesiosis. It is transmitted by a tick, and the protozoan parasites which cause the disease invade the red blood cell.

The possibility of the existence of differences between strains of *Babesia* was investigated by inoculating calves with one of two strains of *Babesia bigemina*. The origin of the two strains ("Y" and "R") has been described previously[2]. The calves were then splenectomized to amplify differences in acquired immunity and, at varying periods after splenectomy, they were challenged with either the homologous or the heterologous strain. Before most challenges, sub-inoculations were made to determine whether the calves were still carrying the original infection. In several instances, this information was obtained after splenectomy, a procedure which provokes relapse in infected animals[3].

Challenge of carriers. A total of nine calves was shown by sub-inoculation to be carrying *B. bigemina* at the time of challenge. When the challenging dose of approximately 10^9 organisms was inoculated intravenously, all developed parasitæmias. In the two receiving a homologous challenge, fewer than 1 per cent of the red blood cells became infected, whereas five of the other seven, which were challenged heterologously, developed parasitæmias within the range of 1–5 per cent. All animals, except one which was anæmic before challenge, controlled their infections without treatment. None of the nine appeared clinically sick during the reaction. As controls, eight splenectomized calves which had not been exposed to *B. bigemina* previously were inoculated with blood used in challenges. Irrespective of the strain used, these calves experienced fulminating infections. Parasitæmias were high, in several instances of the order of 50 per cent. Every calf was treated, but despite this three died.

These results show that splenectomized calves carrying *B. bigemina* are relatively resistant to superinfection with both homologous and heterologous strains, and suggest that a greater degree of resistance is possessed by cattle challenged homologously.

Challenge of animals no longer carrying B. bigemina. Of considerably greater significance were the findings when calves in which the infection had been eliminated were challenged in the same way as the carrier and the control animals. Twenty-nine animals were used in all, and it was possible to make several observations on many of these by repeatedly challenging them homologously before performing a final heterologous challenge (see Table 1 for two examples). In most of these animals, *B. bigemina* had been eliminated naturally some months after the infecting inoculation. Treatment with quinuronium sulphate contributed to the elimination of infection in a few instances. The results of homologous challenges with the "Y" and "R" strains are summarized in Tables 2 and 3, respectively, the results of heterologous challenges in Table 4.

It can be seen that a marked residual resistance was present against homologous challenge with either strain. For the "Y" strain, resistance had developed to a high degree after only one prior exposure to *B. bigemina*, and

Table 1. Repeated Challenges of Splenectomized Cattle which had ceased to carry *B. bigemina* (Two Examples from Series which gave Similar Results)

Animal	Challenge: No. and type	Challenge: Time since last inoc. or challenge (weeks)	Results of challenge: Parasitæmia: Days of	Parasitæmia: Degree of	Clinical effects and treatments	Sub-inoculations: Time after challenge (weeks)	Sub-inoculations: Transmission
578*	1, homol.	16	2	<1%	–	10	–
	1, heterol.	5	3	5%	+, treated second day of reaction	Not done

	3, homol.	12	–	–	–	2	–
	1, heterol.	2	5	15%	+, died despite treatment fifth day of reaction	Not done	

* No reaction to a second homologous inoculation 5 weeks after first homologous challenge, but carrier status unknown at this time.

Table 2. Effects of Homologous Challenge of Animals no longer infected with "Y" Strain *B. bigemina* (after 1 to 6 Prior Exposures)

No. of previous homologous exposures		1	2	3	4	5	6	Totals
Pathological effects from challenge	Parasitæmia with clinical effects	2		1				3
	Parasitæmia without clinical effects	1			3	1		5
	No parasitæmia	6	3	3	3	4	2	21
Carrier status after challenge	Not carrier two weeks after challenge		2	1	1	2	1	7
	Carrier two weeks after challenge			1	4	2	1	8
	No test for carrier two weeks aftet challenge	9	1	2	1	1		14

Table 3. Effects of Homologous Challenge of Animals no longer infected with "R" Strain *B. bigemina* (after 1 to 6 Prior Exposures)

No. of previous homologous exposures		1	2	3	4	5	6	Totals
Pathological effects from challenge	Parasitæmia with clinical effects	2				1		3
	Parasitæmia without clinical effects	1	1		4			6
	No parasitæmia					1	1	2
Carrier status after challenge	Not carrier two weeks after challenge					1		1
	Carrier two weeks after challenge		1				1	2
	No test for carrier two weeks after challenge	3			4	1		8

Table 4. Effects of Heterologous Challenge of Animals no longer infected with Either "Y" or "R" Strain *B. bigemina*

No. of previous homologous exposures	1	2	3	4	5	6	7	Totals
No. challenged	3	1	6	2	1	4	1	18
Parasitæmia with clinical effects	3	1	6	2	1	3	1	17
Parasitæmia without clinical effects						1		1

did not diminish thereafter. Resistance to homologous challenge with the "Y" strain was sufficient to prevent detectable parasitæmia in a total of 21 instances. Further investigations (by sub-inoculation and heterologous challenge) of 15 of these showed that in 7 the animal was not carrying *B. bigemina* two weeks after its homologous challenge. In other words, the homologous challenge had failed to set up a new infection. Results were similar but not so spectacular for the "R" strain.

From Table 4 it can be seen that there was a completely different response to heterologous challenge. These animals reacted severely, and several died despite treatment. The reactions resembled those of the splenectomized controls.

Hence, a sterile immunity has been demonstrated in an infection which has always been presented as a classic example of "prémunition"[4] (co-infectious immunity). It must be pointed out, however, that it is a limited sterile immunity in that it is only effective when the animal has been exposed previously to the challenging strain, and even then not 100 per cent of the animals possess it. This sterile immunity does not exist when a heterologous challenge is performed.

The results also indicate an immunological difference between the two strains of *Babesia* used. A more detailed account of these investigations, the extension of the work to *Babesia argentina* and the epidemiological significance of the findings will be presented elsewhere[5].

ANATOMY

Possible Explosions in Absorptive Cells of the Jejunum

During the course of a long-term investigation of isolated, fresh, absorptive cells of the rat's jejunum suspended in physiological saline, prepared by the method described by Mohiuddin and Ramsbotham[1], we have occasionally come across cells showing a particular abnormality. This consists of a dome-like elevation of the plasmalemma over an accumulation of clear fluid covering one surface of the cell or, at the most, two adjacent surfaces. When this change affects the apex the striated border becomes unrecognizable, probably because the microvilli are taken in by the ballooning plasmalemma. In this respect the condition differs markedly from the transient apical blistering due to rapid pinocytosis reported by Mohiuddin[2].

In cells isolated from animals engaged in digesting fat, the abnormal cells contained fat globules in the cytoplasm, indicating the recent presence of functional capacity. We are satisfied that extraneous factors such as change in tonicity of the saline or pressure of the covership were not responsible for the abnormality, because such cells were usually dispersed among normal cells. We suspect that cells showing such an abnormality might have been observed more frequently if the technique of isolation, which is based on differential centrifugation, was not biased towards elimination of cells of a density differing materially from that of normal absorptive cells.

The appearance of the abnormal cells suggests the imminence of rupture of the ballooned part, although we have not actually witnessed such an end. We are struck by the similarity of appearance between this ballooning and the changes immediately preceding the 'explosions' which seem to occur with such dramatic speed in time-lapse cinemicrographs of cells in cultures.

It is possible that cells as short-lived as the intestinal epithelium (Leblond[3]) are lost not only through the process of shedding, but also in other ways, including 'explosion'.

Location of Renshaw Cells

Ever since their discovery[1], the mammalian spinal cord interneurones known as 'Renshaw cells'[2] have been the object of extensive physiological and pharmacological research[3]. The recurrent inhibitory pathway from motor axon collaterals via Renshaw cells back to motoneurones serves as one of the best-documented examples of a negative feed-back mechanism in the central nervous system. Furthermore, the cholinergic synapses made by the motor axon collaterals on Renshaw cells are the most thoroughly analysed central synapses from the point of view of their pharmacology.

The precise location of Renshaw cells is of considerable interest for the understanding of the functional anatomy of the spinal cord. The electrophysiological investigations of Eccles's group have shown that most Renshaw cells are to be found medial to the motor nuclei[2]. Several investigators have described interneurones just medial to the motor nuclei which might qualify as Renshaw cells[4]. However, recently, interneurones in a still more medial position in the ventral horn have been thought to correspond to the Renshaw cells[5].

In the experiments recorded here, Renshaw cells were located by recording their electrical activity and then marking the position of the tips of the recording electrodes. This provided a physiological control for the histological observations. The preparations used were cats anæsthetized by sodium pentobarbital. The spinal cord was exposed and several ventral roots, usually *L6* and *L7*, were cut peripherally and the central ends mounted on platinum electrodes for stimulation. The recording electrodes were glass micropipettes filled with a solution containing a copper complex, prepared according to the method of Galifret and Szabo[6]. The resistances of the microelectrodes were initially 10–20 megohms, and they were found to be suitable for either extra- or intra-cellular recording.

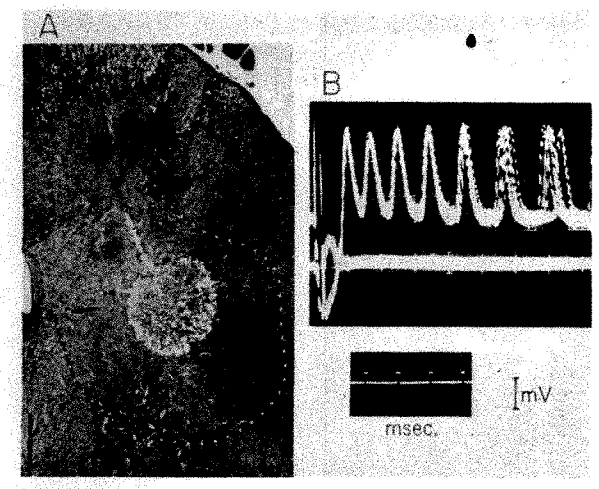

Fig. 1. *A*, Low-power photomicrograph of a transverse section through the lumbosacral spinal cord of a cat. The grey matter has been outlined by a dotted line. In the dorsal part of the ventral horn there is a circular profile corresponding to a lesion produced by copper complex ions which were electrophoretically ejected from a microelectrode, the track of which is seen entering the lesion from its upper left border. *B*, The upper trace shows the characteristic burst discharge of a Renshaw cell in response to ventral root stimulation. The recording was made in a partially intracellular position, positivity being upwards. The stimuli were repeated at 10/sec, and several sweeps of the oscilloscope beam have been superimposed in the photograph. The lower trace was recorded by a monitoring electrode on the cord dorsum. Note the time and potential scales

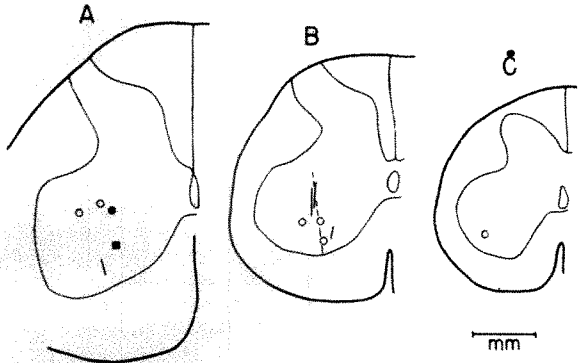

Fig. 2, *A*, *B* and *C* are outline drawings of transverse sections of the lumbosacral spinal cord at three segmental levels. The approximate positions of the various Renshaw cells studied have been marked on these drawings. The filled circle and square in *A* are the locations of two Renshaw cells found in the experiment illustrated in Fig. 1, the circle being the position of the centre of the lesion in Fig. 1*A*. The short lines in *A* and *B* represent the ventralmost extent of microelectrode tracks in those cases in which no lesion was found; the Renshaw cells examined in these instances were presumably just below the ventral tips of these lines. The dashed line in *B* shows the direction of a track in one experiment in which the electrode was partially withdrawn following recording from a Renshaw cell; the neurone was located somewhere along the line and was in the most ventral part of the ventral horn according to the depth readings on the micromanipulator. Note the distance scale

Renshaw cells were sought by systematic tracking within the appropriate segments of the cord. Their characteristic burst discharges in response to ventral root stimulation served to identify them (Fig. 1*B*). Often, recording was at first intracellular. After the electrical activity of a Renshaw cell was observed, the position of the tip of the microelectrode, and presumably of the Renshaw cell, was marked by electrophoretically ejecting copper complex ions from the microelectrode[6]. The microelectrode tip was cut off with a pair of fine scissors and left *in situ* during fixation of the cord with neutral formalin. The microelectrode was then removed, the cord sectioned, embedded and stained. The approximate location of the Renshaw cell was determined by following the microelectrode track into the centre of the large spherical lesion made by the copper complex (Fig. 1*A*). The neurone was assumed to lie at or near the centre of the lesion. Sometimes, no lesion was found, although the microelectrode track was easily traced. Apparently, in these cases, the current passed through the microelectrode was insufficient to allow enough copper complex to leave the microelectrode. Nevertheless, the position of the tip of the microelectrode was noted, since the Renshaw cell must have been located nearby.

Fig. 2 shows the approximate positions of 12 Renshaw cells at three levels of the lumbosacral spinal cord. In addition, the track along which another was found is indicated (Fig. 2*B*, dashed line). The area in which these Renshaw cells were located corresponds to the lateral and ventral parts of Rexed's lamina VII (ref. 7). The Renshaw cells would thus be located near groups of motor axons as they course medially from the motorneurones and then ventrally to join the emerging ventral root filaments. Such a position is obviously a strategic one for interneurones receiving synaptic connexions from collaterals of these motor axons.

RADIOBIOLOGY

Manganese-54 Concentration in Fall-out, Water, and *Unio* Mussels of Lake Maggiore, 1960–63

The ability of *Unio* (Mollusca, Lamellibranchia) to concentrate manganese has been known for more than fifty years[1]. High concentrations of this element in Unionidae were also reported more recently by Vinogradov[2] and by Merlini[3]. In September 1960, manganese-54 was found in *Unio mancus* var. *elongatulus* (Pfeiffer) collected in Lake Maggiore and in nearby Lake Varese. It could not be detected in fall-out, lake water, sediment, rooted aquatic plants, gastropods or fish. After having ascertained that the ^{54}Mn present in *Unio* was not due to local contamination we supposed that this radionuclide must have been present also in the fall-out over northern Italy, but only in very low, undetectable concentrations[4].

^{54}Mn is presumed to originate from the activation of ^{54}Fe and ^{55}Mn present in nuclear weapons[5].

It would seem that because of its ability to accumulate manganese, *Unio* might be used to detect ^{54}Mn contamination of the environment, especially at very low levels which would not be measurable otherwise. To check this, ^{54}Mn was measured in *Unio* as well as in fall-out and lake water during 1960–63.

Lake water and fall-out were sampled as described before[6]. Large samples, at least 100 individuals, of *Unio* were collected at random from the lake bottom. Radionuclide separation of ^{54}Mn and its determination by γ-spectrometry were carried out as reported elsewhere[7]. The standard error of the ^{54}Mn determination was 2–5 per cent for *Unio*, about 10 per cent for fall-out and 10–20 per cent for lake water. ^{54}Mn fall-out increased from 1961 to 1963 (Fig. 1): maximum, monthly ^{54}Mn fall-out (dry + wet), amounting to 22 mc./km^2, occurred in June 1963.

Table 1. Concentration, Content, Percentage and Specific Activity of ^{54}Mn calculated for the Different Parts of *Unio mancus* var. *elongatulus* (Angera, December, 1963)

Stable manganese data are from Merlini[3]

Part	μμc. ^{54}Mn/g Dry wt.	μμc. ^{54}Mn/g Wet wt.	μμc. ^{54}Mn Part	^{54}Mn as % of total	μμc. ^{54}Mn mg Mn
Total body	34·9	13·3	338·0	101	39
Extrapalleal liquid	137·8	0·5	4·6	1	—
Shell	13·4	12·2	117·5	35	40
Total soft tissues	223·4	31·3	215·9	65	30
Gills	366·9	44·0	59·9	18	23
Mantle	280·1	44·0	127·1	38	31
Visceral sac	84·5	13·0	26·8	8	
Foot	32·9	4·0	2·1	1	21

Concentration of ^{54}Mn in surface water of the lake increased from less than 0·01 μμc./l. in September 1960 to a maximum value of 0·60 μμc./l. in June 1963. It decreased thereafter to 0·14 μμc./l. in December 1963. This might be explained by precipitation of insoluble oxidized manganese compounds, absorption by plankton, adsorption by seston, and subsequent settling in the lake bottom[8].

During September 1960–September 1961 ^{54}Mn in *Unio* decreased from 520 to 169 μμc./kg of wet soft tissue, which is 8·5 per cent more than could be expected on the basis of physical decay. This may correspond to a decrease in the specific activity of ^{54}Mn in lake water due to fixation by the sediment. From September 1961 onwards, the concentration of ^{54}Mn increased about thirty-fold to reach 14,000 μμc./kg wet soft tissue in September 1963, which corresponds to a dose to the organism of about 2·3 μrad/h. Calculated fall-out data corrected for decay are reported together with the concentrations in water and *Unio* in Fig. 1. From this, it would appear that *Unio* is a valid bio-index for ^{54}Mn contamination.

Since it was previously found[9] that ^{54}Mn concentration tends to increase with age and size in *Unio*, measurements of length were made for each sample. They revealed a change in population structure from 1960 to 1963, there being an increase in the upper-length classes. On this basis alone, as found by calculating weighed mean concentrations, ^{54}Mn content in *Unio* would have increased by about 11 per cent from 1960 to 1963 if the level of the nuclide in the environment had remained constant. Such an increase is very small compared with the observed increase resulting from changes in concentration of ^{54}Mn in the lake water, but such corrections might be significant under other circumstances and for other species.

The distribution of ^{54}Mn in the body of *Unio* is given in Table 1. The highest concentrations were found in the mantle and gills, the lowest in the extrapalleal liquid.

The distribution of ^{54}Mn in the body was compared with that of stable manganese measured by radioactivation by Merlini[3] (Table 1). The two distributions are strikingly similar although measurements were made on different samples collected at different times. This would indicate that ^{54}Mn was introduced in the lake environment in a form similar to that for stable manganese, from the point of view of availability to *Unio*.

Measurements of ^{54}Mn made on *Anodonta cygnea* indicate that this other genus of Unionidae is also strongly able to accumulate manganese, although the highest value found was one-third that of *Unio*.

BIOLOGY

Axial Organ and Fluid Circulation in Echinoids

The axial organ has long been one of the most enigmatical structures in echinoderms. That of echinoids has been considered excretory[1–4], genital[5], vestigial[6], as producing pigment[7] and as a circulatory organ[8–17].

The idea that the organ functions as a heart is time-honoured and stems from observations of its slow pulsations[17]. Such observations have recently been strikingly confirmed by Boolootian and Campbell[18], who photographed pulsations in the axial organ of *Strongylocentrotus purpuratus*. Contraction, however, is not confined to the aboral extremity of the organ, as sometimes stated for other echinoids, but involves a vessel extending internally along its length.

We have found what appears to be the anatomical counterpart of this vessel in the axial organs of *Arbacia lixula*, *Diadema antillarum* and *Echinus esculentus*. It is not always prominent, however, and it is sometimes difficult to trace through the whole organ.

In the past much misapprehension and argument have arisen from attempts to categorize the axial organ in a simple fashion. In particular, the use of the term 'heart' has been the cause of much contention[7]. It is therefore unfortunate that Boolootian and Campbell report their valuable findings under the somewhat arresting caption of 'a primitive heart' without making it altogether clear whether they are labelling the whole organ or only a part of it. In the context of bygone arguments, such an element of ambiguity can be misleading. Setting aside the more general and fundamental question of the suitability, on embryological grounds, of terms such as 'heart' and 'hæmal' in echinoids, our work on the axial organs of such diverse species as *Arbacia lixula*, *Diadema antillarum* and *Paracentrotus lividus* dispels ambiguity on this particular point, for whatever may be urged concerning the head process, the organ as a whole is pre-eminently glandular. Muscle fibres exist, but apart from those clustered around the stone canal and what appears to represent the pulsating vessel, they are a minor constituent, and over much of the

Fig. 1

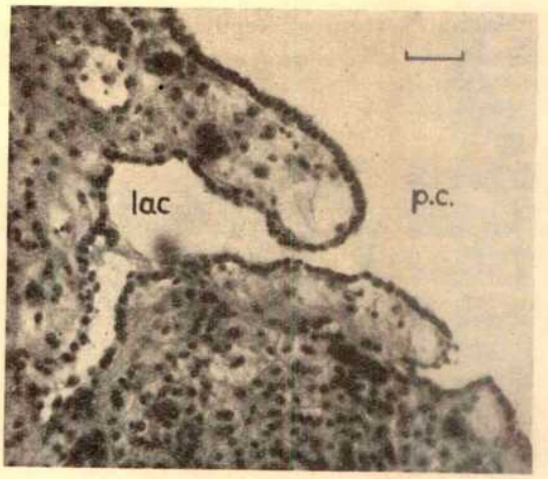

Fig. 2

Fig. 1. *Arbacia lixula*, portion of the axial organ showing an opening into the perivisceral cœlom (*p.c.*) and secretion (*sec.*) which is periodic acid–Schiff-positive, arising from the walls of the glandular recesses of the organ. Rossmann fixation followed by staining with periodic acid–Schiff and hæmatoxylin. Scale as in Fig. 2

Fig. 2. *Paracentrotus lividus*, portion of the peripheral region of the axial organ, showing an opening from the perivisceral cœlom (*p.c.*) into one of the so-called 'blood-lacunæ' (*lac.*), which contains secretion. Rossmann fixation followed by staining with Ehrlich's haematoxylin and eosin. Scale 15μ

organ they are completely lacking. A comparison of the whole organ with a heart is therefore inappropriate.

There is room for second thoughts, however, in making more restricted comparisons with specialized hearts. The capacity to move fluid within vessels of the so-called hæmal system does not endow the axial organ with the status of a heart. No evidence cited as yet indicates that the propulsive agent is localized, or even pre-eminently developed, in the axial organ of echinoids in general. On the contrary, power to pulsate is shared with other vessels, as has long been known[8] and is now re-affirmed (see following).

Boolootian and Campbell claim to have shown the existence of 'a true circulatory system' in *Strongylocentrotus*, which is presumably to be correlated with their description of the uni-directional propagation of contraction through the pulsating vessel of the axial organ. Unfortunately they do not quote details, so that their precise meaning is not clear. We should point out, however, that any view which might attempt to assess the significance of fluid movement in echinoids in general must eventually come to terms with some peculiar features. Thus, as reported in the succeeding communication, some of the so-called hæmal vessels are partially occluded; indeed, those investing the axial organ of *Diadema* are usually completely blocked by dense deposits of melanin and lipofuscin[19]. Again (see following communication) the movement of fluid in parts of the system is of the 'ebb and flow' type[1]. Finally, cardinal regions of the 'circulatory system', including the supposedly central propulsive structures such as the axial organ (with its contained vessels) and stone canal, together with the head process and neighbouring structures such as the madreporite, can be removed completely from living *Paracentrotus*, yet a considerable number of urchins survive the treatment for some weeks, a few for five months. The most consistent and obvious immediate outcome is a local effect on the gut, the inferior loop of which soon begins to degenerate.

It is unfortunate that recent accounts of the axial organ[4,20] have paid little or no attention to a most significant structural feature reported long ago[15], namely, the system of deeply penetrating canals which arise as infoldings of the external surface. Our investigations have shown that their inner end may sometimes be traced into the central lumen of the organ (Fig. 1) or into the network of so-called hæmal vessels that invests it (Fig. 2). Thus, there are a number of direct connexions between the perivisceral cœlom and both hæmal vessels and glandular lumen. In addition, the existence of a communication between the lumen of the axial organ and the stone canal has been re-affirmed[18]. It is now possible to grasp a most essential character of the organ, namely, that it is a central, glandular, point of confluence of perivisceral cœlom, 'hæmal' system and water vascular system. Apart from the controversial relation with the gonads[5,21], it therefore has at least an eminently suitable position to function as an endocrine organ. Sections reveal that considerable quantities of secretion may leave glandular recesses of the organ and pass into the perivisceral cœlom by the canals just mentioned (Fig. 1). Histochemical tests indicate that it is periodic acid–Schiff positive and contains 3-indolyl compounds (possibly tryptophan), together with acid mucopolysaccharide, which also appears in the stone canal and hæmal vessels.

Although it is still uncertain whether the ubiquitous amœbocytes arise in the axial organ, there is abundant evidence that they egest and degenerate within it.

Hæmal System of Regular Echinoids

Examination of accounts of the echinoid hæmal system shows that the term 'hæmal' has never been really justified: its function has not been conclusively demonstrated, and the precise nature of the movement of fluid within the system as a whole has never been satisfactorily established.

Uncertainty even as to the gross anatomy of the system is well illustrated in the instance of the radial hæmal sinuses. Thus Perrier[1] did not describe them, Chadwick[2] could not demonstrate them and doubted their existence. Cuénot[3] affirmed their existence, but admitted that they could not be injected.

Tiedemann[4] first noted the contractile nature of the hæmal vessels. Perrier[1] noted that some vessels of *Echinus esculentus* showed non-rhythmical contraction and thought that the direction of the resultant hæmal flow was not constant. Farmanfarmaian and Phillips[5] could not detect any fluid movement in the hæmal system of *Strongylocentrotus purpuratus*, although a rhythmic beat was observed in the outer sinus (external marginal vessel) and in the collateral sinus of the stomach. Stott[6] considered that, in the absence of a pumping mechanism, distribution of nutrients was effected by migration of amœbocytes within the hæmal system. Boolootian and Campbell[7] have described a contractile chamber and pulsating vessel associated with the axial gland of *S. purpuratus*. They consider that fluid can enter the contractile chamber by two routes, the inner hæmal sinus and also by microscopic ostia. The abstract of the paper states that a pulsating vessel and a compartmented contractile chamber were found to move cœlomic fluid from the perivisceral cavity into and throughout the hæmal system of the urchin. This statement is not fully justified in the account. The authors also state that the rhythmic contraction of the pulsating vessel together with the pulsations of the stone canal may be important in moving fluids through the entire water vascular system.

I have examined the so-called hæmal system of *Echinus esculentus* and *Psammechinus miliaris*. Sea-water contamination was minimized as this causes rapid deterioration of the internal tissues. I can confirm that the collateral and internal marginal vessels of the stomach of both species are contractile, rates of 10 contractions per 60–90 sec being recorded for the internal marginal vessel and 10 contractions per 45–180 sec for the collateral vessel in *P. miliaris*. Particulate matter, principally clumped amœbocytes, was observed through the walls of the vessels. The particles are small and difficult to observe in fresh preparations.

Despite evidence of contractility its significance is not yet clear. First, although some vessels showed a patent lumen (for example, collateral, internal and external marginal vessels of the stomach region), some, such as the peri-œsophageal hæmal ring and the œsophageal vessel, did not, being largely occluded by spongy tissue. Secondly, the particulate contents of the vessels showed ebb-and-flow rather than uni-directional movement, although a net transfer in their position was sometimes achieved. The most usual pathway was as follows: material passed from the œsophageal to the intestinal end of the internal marginal vessel at a rate of about 15 mm/min, and passed along the collateral vessel towards the œsophagus at a similar rate. Net transfer of material from the intestinal to the œsophageal end of the internal marginal vessel simultaneous with collateral flow towards the intestine was also observed but simultaneous flow in both vessels towards the œsophagus or the intestine was not observed.

Pathways available to injected dyes were investigated: it was not possible to inject the œsophageal vessel or the peri-œsophageal hæmal ring as a lumen could not be detected. Neither was it possible to inject the collateral vessel due to its delicate suspension and extreme contractility. Injection into the internal marginal vessel showed that dye passes readily into the collateral vessel when injected from either end of the vessel towards the other, but there is resistance to injection towards the œsophagus. Material injected towards the œsophagus may pass into the origin of the œsophageal vessel, and, similarly, material injected towards the intestine may pass a short way along the external margin of the intestine.

It is concluded that it is unlikely that in these species the so-called hæmal system functions as a true circulatory system. However, there is undoubtedly active movement, and possibly a more restricted circulation, within the vessels of the stomach region. Recent work[5,6] has suggested that absorbed nutrients pass rapidly to the cœlomic fluid. Preliminary experiments, in which the presence of radioactive material was sought in the hæmal vessels after oral injection of isotope-labelled substances in *P. miliaris*, suggest that the hæmal vessels around the stomach may function in absorption, as previously surmised[1,9]. Perhaps they may assist passage of extracted nutrients to the cœlomic fluid, both 'extraction' and diffusion being assisted by the oscillation of fluid within these vessels.

This investigation was conducted, under the supervision of Prof. N. Millott, during the tenure of a Department of Scientific and Industrial Research studentship.

Effects of Histones on Embryonic Development

I have recently examined in detail the effects of actinomycin *D*, an inhibitor of RNA polymerase and of messenger RNA synthesis, on the development of amphibian eggs[1,2]. It is now known that histones also inhibit RNA polymerase[3,4] and it has been suggested that they could act as the natural regulators of genetic activity[5,6]; by combining with specific segments of DNA molecules, they would block the production of messenger RNAs by these segments. It has been suggested[7–9] that such a mechanism could account for the 'switching on and off' of gene activity during embryonic development. It was of interest to compare the effects of exogenous, abnormal histones on embryonic development with those of actinomycin *D*. The latter are quite different from those of another basic protein, ribonuclease, which quickly stops cleavage in amphibian eggs[10], while actinomycin *D* has no effect prior to gastrulation.

The lysine-rich fraction of thymus histones, prepared by the method of Allfrey *et al.*[4], was used in the present work. Three types of experiments were performed on eggs of *Pleurodeles* at various stages of their development: addition of histones to the medium, replacement of the blastocele fluid by a histone-containing solution and micro-injection of histones in just fertilized eggs.

(1) *Addition of histones (3 to 100 μg/ml.) to external medium.* No immediate effect on cleavage could be detected, even at the highest concentrations: when early morulæ or late blastulæ are treated with histones (10–90 μg), development stops at the gastrula stage. A very conspicuous effect of histones (10–30 μg/ml.) is

an intensive contraction of the embryo at the gastrula stage: it leads to exogastrulation and even complete inversion of the cell layers. While the eggs are very sensitive to histones at this critical stage (late blastula–early gastrula), they quickly become insensitive again: late gastrulæ react to histones by a contraction of the neural plate (similar to that observed by Ambellan[11] on addition of ATP to the eggs), while neurulæ are practically insensitive. There is partial reversibility when the embryos are replaced in normal medium: but developmental abnormalities such as microcephaly, cyclopia, complete absence of the nervous system in the extreme cases, *spina bifida*, etc., are frequent in these embryos.

The strong contraction produced by the histones at the critical stage suggests an effect on the cortical layer of the gastrulæ (the absence of ATP in our preparations was of course checked). That histones do not penetrate very deep in the treated embryos was demonstrated by staining slides with fast green, according to the method of Moore[9] for the detection of histones: the vitelline membrane and the external layer of cells stain strongly and a definite gradient in the penetration of the histones can often be observed. Later on, the cells of the superficial layer undergo cytolysis; it is noteworthy that the nuclei and yolk platelets of the dead cells stain much more heavily than those of the normal cells: the latter must, somehow, be protected against the penetration of the histones.

When late blastulæ or early gastrulæ are treated during 5–20 h by concentrated (50–100 μg/ml.) solutions of histones, many cytological abnormalities are seen after staining with Unna or Feulgen. The contraction of the individual cells is visible, with a distortion of the normal gradient in the distribution of RNA. Many cells are multinucleate; all the nuclei are very irregular in shape and size. They contain nucleoli, but their chromatin stains green instead of blue with Unna: it seems that the histones inhibit the synthesis of chromosomal RNA rather than that of nucleolar RNA. The mitoses are usually numerous, with a tendency towards a block in metaphase. It is likely that multinucleate cells result from two different processes: amitosis and lack of cytodieresis due to the strong contraction of the cells, and lack of fusion of the chromosomes at telophase. When the blocked gastrulæ are replaced in normal medium the nuclei soon resume their normal staining (blue chromatin, red nucleoli) characteristics.

(2) *Injection of histones in the blastocele fluid.* The effects depend very much on the concentration of histones used, all the embryos reacting in almost the same manner to a given concentration. At the 1 μg/ml. level, all embryos[9] formed abnormal tadpoles. After injection of histones at a 2 μg/ml. concentration, 7 abnormal neurulæ (out of 7 injected blastulæ) were obtained; with 4 μg/ml., the block of development was practically immediate in all[9] the injected blastulæ.

Cytological investigations showed that, after the injection of histones (2–4 μg/μl.), the cells surrounding the blastocele have large nuclei, which stain green with Unna and have no visible nucleoli: obviously, the block in DNA and nuclear RNA synthesis is complete in the cells which have been directly exposed to the histones. In the outer layers, one can find a mosaic of normal and abnormal (irregular shape, larger size) nuclei.

(3) *Injection of histones* (1 μg/ml.) *at the one-cell stage.* Out of 13 injected eggs, 8 failed to divide, probably as a result of the injury. The 5 others cleaved normally, but stopped developing at the late blastula stage. They displayed the usual nuclear abnormalities. In one case, an egg was injected in one of the blastomeres at the 4-cell stage and fixed 8 h later, as a normal morula. It was cytologically normal, except for the two blastomeres corresponding to the injection point: they contained huge, swollen nuclei, apparently blocked in interphase, which remained unstained with Unna.

In conclusion, it can be said that the effects of histones present, as one would expect, great similarities with those of actinomycin *D* (refs. 1, 2, 12): cleavage—but not gastrulation—is possible after injection into fertilized eggs, and it is not affected by histones added from the outside. Exogastrulation, as found by Wallace and Elsdale[12] in the case of *Rana pipiens* eggs treated with actinomycin *D*, is very frequent. Abnormalities, such as microcephaly, become conspicuous at later stages: they are identical with, but not so extensive as, those produced by actinomycin *D*. The difference is probably due to a poorer penetration of the histones. Regarding the effects on cleavage, histones are much less effective than ribonuclease[10]: it is therefore probable that the inhibition of cleavage by ribonuclease is due to its enzymatic activity and not to its basic character.

I thank Miss E. Van Stevens for making the microinjections, and Prof. E. Schram, who prepared and analysed the histones. This work was supported by Euratom (contract 016–61–10 *ABIB*).

Light as an Inhibitor of Strobilation in *Aurelia aurita*

The environmental conditions under which strobilation of *Aurelia* scyphistomæ occurs are incompletely understood. Berrill[1] in a review suggests three factors as being of particular significance: a heavy diet of suitable food prior to metamorphosis; a definite, low critical temperature, usually the winter minimum; and a good supply of food and oxygen at the critical period. Thiel[2], as a result of observations on naturally-occurring populations of scyphistomæ, largely supports these suggestions and places particular emphasis on the food supply prior to strobilation. Laboratory experiments have produced conflicting results[3].

A series of experiments was arranged to investigate the effects of these environmental conditions on strobilation in the laboratory. Scyphistoma larvæ were selected from stocks reared from planulæ released by adult *Aurelia aurita* collected at Whitstable. These larvæ were put in vessels which in turn were placed in a low-temperature water bath. The temperature of the bath was gradually lowered from 11° C to 5·25° C during a period of 2·5 months. The larvæ were fed twice a week on *Artemia* nauplii throughout the experiments. Initially all the larvæ were under 6 h daily illumination from a 3-ft. Osram 30 W warm white fluorescent tube at a distance of 26 in. The results of transferring some larvæ into the dark while leaving others in the light as control are shown in Table 1.

These results indicate that the presence of light of too high an intensity inhibits strobilation. With the exception of '63/*A*, strobilation only occurred in the absence of light. This interpretation does not necessitate that all larvæ in the dark should strobilate, and therefore experiments '63/*E*, '63/*H* and '63/*I* are not necessarily unsatisfactory. The apparently anomalous result in '63/*A* can perhaps be explained by the fact that all specimens

which strobilated belonged to the same group of larvæ which were attached to the underside of a shell and were therefore shielded from direct light. The failure of strobilation to take place in '63/*E*, *H* and *I* could be attributed to fundamental differences in the tissues of the larvæ. Two such factors which could account for these results are the size of the food reserves and the age of the individuals. Although specimens were selected from a stock population which had been derived from the same batch of planulæ, there was no way of identifying those scyphistomæ which had developed directly without budding from those which had resulted from asexual reproduction. Again, although specimens were selected which were initially the same size, it was noticeable that strobilation ultimately occurred most readily among the larger individuals.

'63/*S*		+	−		6	0	−	−

*The temperature listed in each case is the point during the gradual lowering to 5·25° C at which specimens were transferred from the light into the dark. The exceptions are Exps. *R* and *S* which were maintained at 11°–13° C as a control.

† These figures show the extreme range of intervals in days between the start of the experiment and the onset of strobilation in those specimens which metamorphosed.

If light is an inhibitory factor, then the progressive fall in illumination[4] which occurs in late autumn might be a positive stimulus for the onset of strobilation. Such a fall occurs simultaneously with the lowering of temperature at that time of the year[5]. Although there is a record of the appearance of ephyræ larvæ in the plankton at various stations along the coast of northern Europe during January–April[6], there are no direct observations on the onset of strobilation at these points. This suggests that strobilation must have started some 3–6 weeks earlier than the appearance of these ephyræ, that is, late November–March—a time when values of illumination and temperature are both low. It should be noted further that scyphistoma larvæ tend to settle on the underside of rocks and shells where there is a low level of illumination; and that the sediment in coastal waters is often responsible for blocking the light to a greater or lesser degree. It is suggested that light of too high an intensity may have contributed to the failure of earlier experiments designed to induce strobilation under laboratory conditions.

Growth of Embryos of *Amyema*, *Amylotheca*, and *Scurrula* on Synthetic Media

We have already reported[1] the growth responses of globular and complete embryos of *Dendrophthoe falcata* (L.f.) Ettings. These investigations have now been extended to *Amyema pendula*[2] (Sieb. and Spreng.) van Tiegh., *Amylotheca dictyophleba*[2] van Tiegh., and *Scurrula philippensis*[2] (Cham. and Schlecht.) G. Don.—all members of the Loranthaceae.

The mature embryo has a broad hypocotyl but has no radicle. The cotyledons are closely appressed to each other giving a pseudo-monocotyledonous appearance in *Amyema* and *Scurrula*, but they are mostly free in *Amylotheca*. The hypocotyl of *Amyema* is studded with papillate outgrowths (Fig. 1,*A–C*), while that of *Amylotheca* shows finger-like projections (Fig.1,*D*).

The fruits were surface sterilized with chlorine water for 10–15 min and washed thoroughly with sterile water. The embryos were excised and sown on sterile modified White's medium[3] under aseptic conditions. The *p*H of the medium was adjusted to 5·6. The cultures were maintained at 25° ± 2° C.

For purposes of comparison we may briefly recapitulate the results previously obtained with the mature embryos of *Dendrophthoe*[1]. The embryos (4–8 mm long) planted on modified White's medium supplemented with indolyl-3-acetic acid (IAA) (0·5 p.p.m.) + casein hydrolysate (500 p.p.m.) developed a superficial meristem around the hypocotyl and produced a discoid holdfast within five weeks. Eight haustorial disks developed in succession during the next 10–15 weeks. The plumular leaves emerged 4–5 weeks after inoculation and 25-week-old seedlings were about 3·5 cm long with three pairs of leaves. When the embryos were cultured with intact endosperm, the unfolding of the plumular leaves was delayed or altogether inhibited.

The embryos of *Amyema* (2·5–4 mm long) were sown on White's medium + IAA (0·5 p.p.m.) + casein hydrolysate (500 p.p.m.). Within a week the embryo turned dark-green, and the hypocotyl elongated and swelled appreciably. In 3–5 weeks after inoculation the hypocotyl developed a marginal meristem which gave rise to an irregular, massive, discoid holdfast (Fig. 1,*B*). The first pair of plumular leaves also appeared at this time, and in another 10–15 weeks three pairs of leaves were formed. In nearly 10 per cent of the cultures the papillate outgrowths became very prominent and during the next 15 weeks they simulated the later stages of embryonic development in Nature. Finally, they produced multiple shoots (Fig. 1,*C*). When the nutrient medium was supplemented with autoclaved coconut milk (10 per cent, v/v), the basal end of the hypocotyl (radicular end) and localized areas of cotyledons produced friable callus masses.

On White's medium + IAA (0·5 p.p.m.) + casein hydrolysate (500 p.p.m.) the embryos of *Amylotheca* (4–6 mm long) attained almost double the length in 3-week-old cultures. The finger-like processes (Fig. 1,*D*) elongated considerably but failed to produce shoots. The cotyledons mostly withered and abscissed in eight weeks. 25-week-old seedlings showed a pair of leaves, a holdfast and 2–5 haustorial disks.

The embryos (2–3 mm long) of *Scurrula* were also cultured on White's medium + IAA (0·5 p.p.m.) + casein hydrolysate (500 p.p.m.). The first pair of plumular leaves was noticed in 5-week-old cultures and three pairs of plumular leaves developed within the next 15 weeks. In one instance a sucker also developed from the holdfast (Fig. 1,*E*). If cultured with intact endosperm, the embryos germinated only rarely.

It is concluded that the embryos of the semi-parasitic mistletoes can be easily grown on synthetic media. With the endosperm intact, the appearance of plumular leaves

is usually delayed or inhibited. However, the holdfast and the haustorial disks develop normally. The papillate outgrowths on the hypocotyl of *Amyema* represent vegetative buds and differentiate into multiple shoots. Probably this is also true of the finger-like outgrowths on the hypocotyl of *Amylotheca*.

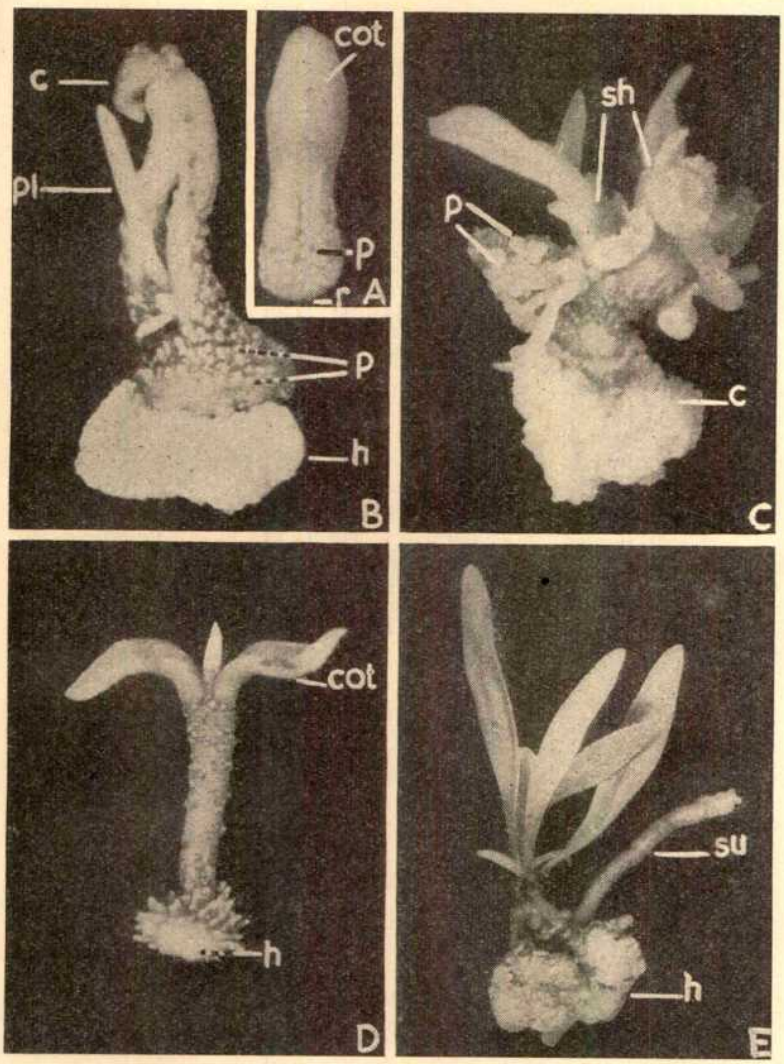

Fig. 1. *A–C, Amyema pendula: A*, mature embryo; note the papillate outgrowths on the hypocotyl (× *c.* 11); *B*, 5-week-old seedling showing a holdfast and plumular leaves, on White's medium + IAA (0·5 p.p.m.) + casein hydrolysate (500 p.p.m.) (× *c.* 3·6); *C*, 15-week-old proliferated embryo on White's medium + coconut milk (10 per cent) showing various stages of differentiation of the papillæ into shoots (× *c.* 3); *D*, 5-week-old seedling of *Amylotheca dictyophleba*; note the free condition of cotyledons and the elongation of the finger-like outgrowths (× *c.* 5·3); *E*, 20-week-old seedling of *Scurrula philippensis* with a massive holdfast, sucker and leaves (× *c.* 2). Key: *c*, callus; *cot*, cotyledon; *h*, holdfast; *p*, papillate outgrowth; *pl*, plumular leaf; *r*, radicular end; *sh*, shoots; *su*, sucker

ENTOMOLOGY

Effects of High Temperature in *Rhodnius prolixus* (Stål).

Rhodnius fourth instar larvæ fail to moult at a temperature higher than 35° C; and at this temperature, or slightly lower, there is a disturbance in the hormone balance[1]. This communication deals mainly with the results of exposing the different larval stages, directly after feeding, to 36·5° C for different periods, and then transferring them to 28° C, the optimum temperature. Such treatment results in delayed moulting in all the larval stages, and in a reduction in the numbers of sensory bristles and plaques which are differentiated and in their malformation. If the insects are kept at the high temperature before feeding, the same symptoms appear; there is also inhibition of the diuresis which normally takes place during the first 4 h after feeding[2], despite the apparently normal functioning of the Malpighian tubules.

Wigglesworth states that, although high temperature (36° C) may have an adverse effect on the secretion of the brain factor, since the thoracic glands show no signs of activity, it may also arrest moulting by interfering with the secretion of the thoracic gland hormone or its action on the epidermis[3]. By combining heat treatment, transfer experiments and decapitation experiments with histological investigations, it has been shown that the brain hormone is not secreted at high temperature and that, after transfer to the optimum temperature, its secretion is delayed. This results in a delay in the activation of the thoracic gland, which is the main target of the brain hormone, and in the mitotic activity of the epidermal cells; hence moulting is temporarily arrested. High temperature was found to interfere with wound healing at the stage of mitosis. This would explain the cessation of moulting, at 36° C, in larvæ injected with ecdysone, or in larvæ supplied with the hormone in parabiotic experiments[3]. Thus it is concluded that, even in the presence of the moulting hormone, moulting does not occur at high temperature, because of the effects of the latter on cell division. Moreover, at 28° C, the oxygen consumption of decapitated injured larvæ shows a maximum increase of about two-fold at five days after injury—a time corresponding to the maximum growth activity in the epidermis during wound healing[4], whereas at 36·5° C there is no increase in respiration.

Examination of proteolytic activity in the midgut of fifth instar larvæ showed that the optimum *p*H is 3·55 and that 84 per cent of the total activity is found in the lumen contents. At high temperature, proteolytic activity is normal until 2 days after feeding; it then decreases to reach a very low level 7 days after feeding. In the insect decapitated 4 h after feeding and kept at 28° C, the level is normal 2 days after feeding, remains constant, and by 8 days after feeding it decreases. This agrees with Thomsen and Møller's results on the influence of the median neurosecretory cells of the brain on protease activity in *Calliphora erythrocephala* Meig[5].

Seven days after feeding, the concentration of total free amino-acids in the hæmolymph at 36·5° C is approximately twice that at 28° C. Conversely, the abdominal fat body

protein content and the hæmolymph protein concentration are much less at high temperature. Directly after transfer to the lower temperature, the amino-acid concentration decreases, while the fat body and hæmolymph proteins and the protease activity in the midgut start to increase. If the insects are decapitated immediately after transfer, the hæmolymph amino-acid concentration does not decrease to the normal level, even 13 days after transfer. However, even after transfer to normal temperature, the levels of these metabolites and of oxygen consumption do not revert to normal; this is correlated with the longer period required for development under these conditions.

It is concluded that high temperature interferes mainly with protein synthesis. This is reflected in the inhibition of cell division, the impairment of differentiation, the reduction in midgut protease activity and the cessation of secretion of the brain hormone which may prove to be a protein or a proteinaceous compound. This compares with Wigglesworth's suggestion that the characteristic defect in the resting or dormant insect, where no moulting hormone is being secreted, is a failure of protein synthesis[6].

Preliminary investigations on the inhibition of reproduction in both sexes at high temperature revealed signs of inactivity of the corpus allatum.

A Large Amount of Trehalose in a Frost-resistant Insect

With a few exceptions[1], almost all the remarkably frost-resistant insects have been shown to contain glycerol or sorbitol[2]. The overwintering pre-pupal larvæ of a sawfly, *Trichiocampus populi* Okamoto, however, were found to survive freezing at a liquid gas temperature without any polyhydric alcohol. An extraordinarily large amount of a sugar, trehalose, was detected in this insect.

T. populi is one of the common pests of poplar trees. The full grown larvæ of this insect leave the food-plant in autumn and pass the winter as prepupæ in withered plants. The body weights of the prepupæ were more than 30 and 80 mg in male and in female respectively. Since some of them are found in small holes or slits in the twigs of some trees or shrubs, and remain uncovered by snow during the coldest season, they are exposed to severe cold. In fact the overwintering prepupæ were found to survive freezing at −30° C for many days. As the supercooling point in the prepupæ is −8·6° ± 0·4° C, and the highest freezing temperature is about −3° C, they conceivably freeze and thaw many times during the winter.

Our earlier work showed that an animal could survive freezing even at liquid gas temperatures provided it could withstand prefreezing at −30° C (refs. 3 and 4). Our prefreezing method was also applied to the overwintering prepupa of *T. populi*. Four groups of ten prepupæ were subjected to freezing in air at −30°, −25°, −20° and −15° C respectively for 1·5 h. One other group was also frozen at −30° C as control. All groups of the insects, except the control, were then immersed directly in liquid nitrogen. After being kept there for 2 h they were rewarmed in air at −30° C for 30 min, and transferred into air at room temperature. As shown in Table 1, the prefreezing treatment at temperatures below −20° C were sufficiently effective to enable the insect to withstand a very low temperature. It is of interest that pre-freezing proved to be as effective at −20° in the sawfly prepupa as at −30° C, because in extremely frost-resistant insects so far known, pre-freezing has been found to be far less effective at a temperature above −25° C than at −30° C. After re-warming from the liquid nitrogen temperature, most of the prepupæ survived for more than 100 days. Many of them were able to resume development even up to the formation of the imago, but could not shed their pupal skins. This was also the case in other insects in which our pre-freezing method had been successfully applied.

Table 1. Prefreezing Temperature and Survival in the Sawfly Larvæ after Cooling to and Thawing from the Liquid Nitrogen Temperature

	Prefreezing at (° C)	Prefreezing for (h)	No. insects used	No. surviving insects
Control*	−30	4·0	10	9
1	−30	1·5	10	9
2	−25	1·5	10	10
3	−20	1·5	10	10
4	−15	1·5	10	0

* Prefreezing only.

The possession of small-molecule neutral substances has been thought to favour survival during freezing[2,5]. The protective substance has been shown to be sugar, mainly sucrose, in higher plants, and polyhydric alcohol, mainly glycerol, in insects. No glycerol was found in the prepupa of *T. populi*, in which a remarkably large amount of sugar was detected. The total sugar content of the overwintering prepupæ ranged from 5 to about 9 per cent of the fresh body-weight (average more than 6·3 per cent). It was nearly constant throughout the 4 months cold season. The termination of diapause, therefore, seems to have no direct effect on the high sugar content in this insect, because the prepupæ were generally released from diapause by the beginning of January.

The sugar in the prepupæ was identified by a chromatographic method[6]. In midwinter about 97 per cent of the sugar content was the non-reducing disaccharide, trehalose, which has recently been shown to be the major blood sugar in a variety of insects[7]. As the water content of the prepupa of *T. populi* was found to be about 65 per cent, the concentration of sugar in solution in the insect must be about 9 per cent. So far as we are aware, this is a higher concentration of trehalose than has previously been recorded in any insect. The concentration of sugar in these sawfly larvæ is comparable with that of the sum of polyhydric alcohol and sugar in very frost-hardy plants[8].

MICROBIOLOGY

Lysogenic Conversion in *Staphylococcus aureus*, to a Change in the Production of Extracellular 'Tween'-splitting Enzyme

Observations on death or survival of 554 patients with staphylococcal bacteræmia[1,2] indicated a correlation between virulence in this situation and the lack of diffusible extracellular lipase as investigated on 'Tween'/calcium agar plates. Therefore an attempt was made to discover whether the negative lipase reaction was a

marker for other properties of the strains, for example, a lowered membrane permeability or a factor inhibiting the lipase or blocking the production of this enzyme.

The approach to this problem included a survey of 10,000 strains from 10,000 persons, 1,507 of which were phage type 80/81, and 235 lysed by typing phage 80 only. In the former group 15 per cent were 'Tween' negative (*TW*−), as against 80 per cent in the latter group, which suggested a connexion between the negative 'Tween' reaction and a loss of sensitivity to phage 81, possibly due to lysogenization[3,4].

In order to investigate this possibility we isolated, using the chloroform method described by Kjems[5], from a *TW*-type 80 strain, a phage (24724′) which lysed a *TW*+ type 80/81 strain. All 40 colonies from surviving bacteria of the latter strain after exposure to the filtrate of phage 24724′ (titre 10^9/ml.) were by means of replica tests[6], demonstrated to be lysogenic for phage 24724′, resistant to phage 81, and to be *TW*−. In repeated experiments 84–87 per cent of the cells from the receptor strain cells were lysed, and the remaining colonies were all lysogenic and *TW*−.

A phage with converting properties similar to that of phage 24724′ was isolated from each of a further four *TW*− type 80 strains examined. A phage isolated from a *TW*+ type 80 strain was able to lysogenize the receptor strain and change the type from 80/81 to 80, but—as expected—did not cause any change of the 'Tween' splitting ability.

Conversion experiments with phage 24724′ were made using 20 *TW*+ type 80/81 receptor strains. In all cases the phage-resistant colonies were lysogenic for 24724′, had lost sensitivity to typing phage 81, and were 'Tween'-negative.

Furthermore, in several instances it was possible to detect *TW*+ mutants in those *TW*− type 80 strains carrying converting phages; on examination these proved to be non-lysogenic phage type 80/81.

It was concluded that the negative 'Tween' reaction in the type 80 strains investigated was due to lysogenic conversion, as: (1) all lysogenic colonies were *TW*−; (2) the conversion occurred even when the converting phages were propagated on a *TW*+ strain; (3) loss of the converting phage caused a reversion to *TW*+.

This evidence suggests that the presence of a prophage may influence virulence in *Staphylococcus aureus*. However, it has not been shown whether changes in the bacterial membrane or factors altering the enzyme production are responsible for the negative 'Tween' reaction.

Production of Aposymbiotic Cockroaches by means of Lysozyme

IT has long been known that special cells (bacteriocytes) within the abdominal fat body of the cockroach are packed with rod-shaped bodies presumed to be symbionts[1]. This intracellular symbiosis, obligatory in Blattariae, is unusual in that cockroaches are omnivorous and symbionts occur predominantly in insects the diet of which is deficient in certain essential nutrients. The production of symbiont-free cockroaches, so-called aposymbiotic insects, is an aid to the investigation of the significance of the symbiosis. Several authors[2–5] have reported the elimination of the cockroach symbionts by feeding or injecting antibiotics and bactericidal drugs.

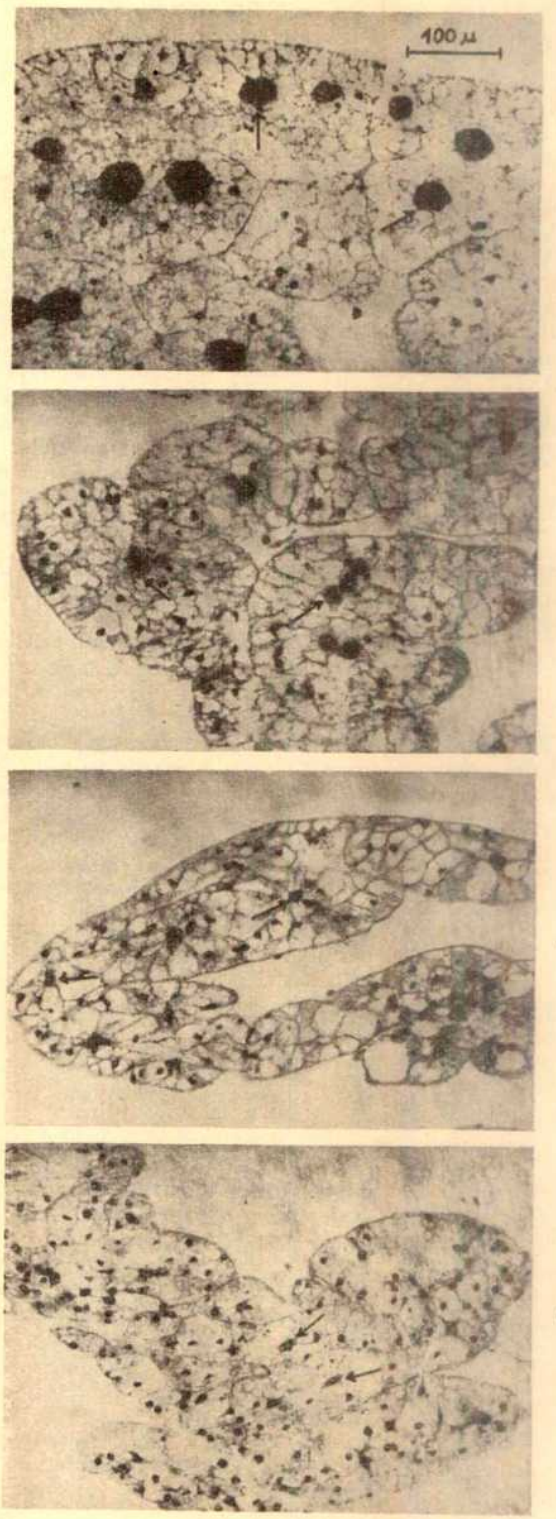

Fig. 1, *a–d*. Photomicrographs of sections through the abdominal fat body of *Periplaneta americana* L. nymphs. Fixed in Bouin's fluid and stained with Giemsa's solution; cut at 8μ. Photographs were made with objective 10, eyepiece 6·3, and a green VG 4 filter (Carl Zeiss, Jena). The magnification is the same throughout. Arrows point to some of many bacteriocytes in the fat body. (*a*) Normal NaCl-treated control. (*b*) 25 days after the first lysozyme injection. (*c*) 70 days after the first lysozyme injection. (*d*) 123 days after the first lysozyme injection

However, it is always difficult to say whether this treatment produces deleterious effects on the insects or whether abnormal reactions by the host are due to loss

of symbionts. Furthermore, Brooks[6] emphasized that complete elimination of symbionts is out of reach unless the dose is high enough to kill the host, and concluded that "the only way to obtain aposymbiotic insects is by preventing the original infection in the offspring".

In a previous paper[7], I have suggested that the symbionts of the cockroaches are lysozyme-sensitive and therefore are lysed by the enzyme. In the present experiments, 1 per cent lysozyme from egg white in 0·5 per cent NaCl solution was injected directly into the body cavity of the nymphs in three 0·05 ml. doses at 3-day intervals. Control animals received only 0·5 per cent NaCl solution. The condition of the bacteriocytes and their symbionts was examined by phase contrast observation of smear slides of the fat body and, after fixation in Bouin's fluid, sectioning in paraffin and staining in Giemsa's solution.

Fig. 1*a–d* shows the results. It can be seen that the symbionts disappear under the influence of lysozyme. The bacteriocytes become depopulated and smaller in size, but their nuclei remain clearly visible and do not shrink. As a rule, one injection is sufficient to disintegrate all the symbionts within a few days, but cell débris is still seen months afterwards. Normal bacteriocytes become deep blue in Giemsa's solution whereas lysozyme-treated bacteriocytes get a reddish colour and only their nuclei remain blue-stained.

The method has the following advantages: (*a*) lysozyme is not toxic; the mortality is as low as among the NaCl controls. Even in extremely high concentrations (22 injections) the insects tolerate this agent; (*b*) unlike antibiotics, lysozyme affects resting cells, and so eliminates the symbionts more rapidly; (*c*) lysozyme resistance has not been observed; this implies that all the bacteria are apparently killed, leaving no residue to repopulate the insect; (*d*) the loss of the symbionts is demonstrable in the treated generation and not only in their offspring.

Isolation and Significance of *Streptococcus faecalis sensu strictu*

In an earlier communication[1] a medium was briefly described which had been developed at the Laboratories of the Metropolitan Water Board for the isolation of certain strains of *Streptococcus faecalis* with a combination of attributes which offered the possibility of distinguishing fæcal pollution of predominantly human origin in some climatic regions. Strains which possess the distinctive characteristics of simultaneous high tyrosine decarboxylase activity on a sorbitol substrate and the ability to reduce tetrazolium chloride to formazan may be isolated on the thallous acetate medium which selectively demonstrates the presence of these organisms.

The possible use of the characteristics of high tyrosine decarboxylase activity for distinguishing strains of *Strep. faecalis* from other Group D streptococci was apparent from a consideration of the findings of Sharpe[2]. In an analysis of human-derived strains of fæcal streptococci Sharpe revealed that strains of *Strep. faecalis* var. *faecalis* and the varieties *zymogenes* and *liquefaciens* could be grouped together on the basis of a high tyrosine decarboxylase activity, and that other species and unclassifiable intermediate strains of Group D streptococci possessed little or no tyrosine decarboxylase activity. Moreover, the activity of the enzyme was clearly associated with other biochemical characteristics, and no raffinose-fermenting strains were encountered which produced this enzyme. Hence, high tyrosine decarboxylase activity was associated with biochemically more 'typical' strains which have been referred to in the present investigation as *Strep. faecalis sensu strictu*, and since Sharpe did not further sub-divide her strains to distinguish *Strep. faecium* from *Strep. faecalis* it was necessary to include the criterion of tetrazolium chloride reduction for this purpose in the tyrosine isolation medium since it is known that some strains of *Strep. faecium* possess the ability to decarboxylate tyrosine.

Investigation of the extent to which strains of *Strep. faecalis sensu strictu* are restricted to the human alimentary tract, and the implications of this restriction, in assessing the origin of fæcal pollution, is continuing. As the relative predominance of *Strep. faecalis* in the human gut is probably related to diet[3] it is highly probable that the incidence of strains with high tyrosine decarboxylase activity is also affected by the constitution of the diet, so that the significance of *Strep. faecalis sensu strictu* in assessing pollution may differ in different countries. This fact does not suggest a hard-and-fast yardstick by which all human-derived strains of *Strep. faecalis* may be separated from all animal-derived strains. This is a possibility which may be realized in the heat tellurite test[4,5] for those strains which are heat-resistant, though for the purpose of an ecological survey of bacteria it is a considerable advantage to have the use of a direct isolation medium for selecting certain organisms by easily recognizable characteristics. The heat-tellurite test is a relatively lengthy procedure demanding pure cultures and particular attention to certain technical details[6,7].

A recent communication by Mundt[8] prompts me to reiterate in greater detail some of the points made in my original contribution together with a reference to some supporting experimental results which will be published more fully at a later date. Mundt has equated the use of the term *Strep. faecalis sensu strictu* with the variety *Strep. faecalis* var. *faecalis*, although this was not implied in the original usage which is independent of varietal status. In fact it has been suggested that the designation of varieties within this species be discontinued following the recent detection of a more widespread proteolytic ability among strains of *Strep. faecalis* and *Strep. faecium*[10], and the long-recognized instability of the property of hæmolysis in certain strains. These findings are contrary to the arguments in favour of attempting to recognize consistently definable varieties on the basis of only two unreliable characteristics. Thus, it is surprising that Mundt distinguishes *Strep. faecalis* var. *liquefaciens* as a separate species.

There is scope for a new approach to the problem of separating human- from animal-derived strains. For this purpose there are some possibilities arising from the results concerning *Strep. faecalis sensu strictu* presented in Table 1 in which the percentage distribution of the organisms has been determined in the fæces of 50 individuals from each of a number of animal species and man. The animals are those species which are most likely to pollute water or milk supplies[4], including wild birds. A significantly higher incidence in man of *Strep. faecalis sensu strictu* and in fact of all strains showing high tyrosine

Table 1. Isolation of *Streptococcus faecalis* from 50 Individuals from Each Host

Host	No. of individuals with *Strep. faecalis sensu strictu*	No. of individuals with colonies of all types showing high tyrosine decarboxylase	No. showing no growth	% of Individuals with *Strep. faecalis sensu strictu*
Man	26	26	4	52
Cattle	2	3	8	4
Sheep	4	8	2	8
Deer	6	16	4	12
Rabbit	5	12	23	10
Bird	4	8	15	8

decarboxylase activity on the tyrosine medium may be noted. Quantitative results for *Strep. faecalis sensu strictu* have also been obtained varying from 0 to $18{\cdot}4 \times 10^4$ per g of fresh fæces for human material and 0 to $7{\cdot}46 \times 10^2$ per g for sheep and cattle.

The finding of Mundt that not all human-derived strains of *Strep. faecalis* are able to produce high tyrosine decarboxylase activity is in agreement with the findings in the present investigation, and seemed likely from an examination of Sharpe's earlier results[2]. However, it is suggested that the greater frequency of *Strep. faecalis sensu strictu* in human fæces than in that of most animals may be best exploited in quantitative determinations, the possibilities for which have been referred to elsewhere[11]. The results so far obtained apply to the distribution of *Strep. faecalis sensu strictu* in this country only, which may be different from other regions with a more widely-ranging fauna and/or different dietary habits among the human population.

Mundt[8] has also raised some criticisms relating to the use of the tyrosine medium for the quantitative recovery of strains of *Strep. faecalis* when compared with the medium of de Man, Rogosa and Sharpe (MRS) and using pure cultures of the test organisms. The anomalous results obtained suggest that a 1 per cent concentration of thallous acetate may have been employed instead of 0·1 per cent, owing to an error in the published formulation of the medium which was subsequently corrected (in reprint copies of the communication). A comparison between the highly selective tyrosine medium (thallous acetate + sorbitol) and the rich and completely non-selective MRS medium designed for the cultivation of lactobacilli is of little practical value. In the present investigation a comparison has been made between the tyrosine medium and that of Barnes[12], which is used at the same *p*H and includes the same selective inhibitor as the tyrosine medium. From a range of 20 fæcal samples from various sources the results obtained were as follows: in 9 samples a significantly higher total yield of colonies was isolated on the tyrosine medium; in 4 samples Barnes's medium produced a greater yield, while the remaining 7 samples gave comparable results by both methods. However, it is possible that subsequent improvements may be made in the quantitative recovery of *Strep. faecalis* by the tyrosine medium. The necessity for resuscitation at 37° C prior to incubation at 45° C has been emphasized already[13], particularly when attenuated strains are to be isolated from water.

The isolation of *Strep. faecalis sensu strictu* is not an exclusive index of human fæcal contamination in all situations, but in certain instances it can yield valuable evidence in assessing the origin of pollution. The necessity for future investigations in this field is pointed to in the words of a recent review[9]: " . . . continued study with the streptococci is necessary in regard to the development of specific media for species isolation, and their incidence under field conditions in various water supplies. . . ."

CYTOLOGY

Sedimentation Rate of Cells in Metaphase as compared with Cells in Interphase

In recent years there has been considerable interest in the study of the chromosome complement of malignant tumours. In most of these investigations culture techniques have been utilized. Direct methods of study have an advantage in that there can be no questions of selection of particular clones that happen to proliferate better in *in vitro* conditions. Direct methods have worked well in examination of bone marrow and neoplastic effusions. However, study of solid neoplasms has been hampered by the fact that usually only a few metaphases suitable for karyotyping can be obtained from any given tumour.

During the course of investigations of solid neoplasms we noted considerable variation in the number of metaphases from slide to slide prepared from the same suspension, and decided to see if such variation might be due to a difference in sedimentation rate of cells in interphase and metaphase. If such a difference existed, advantage could be taken of this to concentrate cells in metaphase for examination. The following experiments were designed to detect any such difference.

Leucocyte cultures were prepared from peripheral blood by standard techniques. (We thank Dr. William Mellman of the Department of Pediatrics, Hospital of the University of Pennsylvania, for providing us with many of the chromosome preparations used in these experiments.) All glassware used in the experiments was siliconized. Heavy cell suspensions of cultured leucocytes in Carnoy's fixative were thoroughly mixed to obtain uniform distribution of cells. Five capillary blood coagulation tubes (Precision grade, Drummond Scientific Co., Cat. No. 1200) were partly filled with the cell suspension by capillary action. The capillary tubes were pre-calibrated so that the volume of any given column of liquid could readily be calculated from the formula:

$$V = 3{\cdot}1416\, r^2 \times L$$

where V = volume of fluid (ml.),
r = internal radius of the tube (cm)
L = length of liquid column (cm)

One of the five tubes served as a control and the remainder were placed in a vertical position in 'Seal-Tube Paste' (Clay-Adams, New York) and allowed to sediment for 5, 10, 15 and 20 min.

At the end of each period the tube was removed from the paste and placed in a horizontal position, and the sealed end of the capillary together with any sediment that may have been present was discarded. The length of the remaining liquid column was measured, the volume calculated, and the entire contents were expelled on to a wet, pre-cooled slide with the aid of small rubber bulb. The cell preparation was spread on the slide by the 'flame' technique making certain no significant quantity of material was lost through spillage and that the cell suspension was spread over a relatively small area of the slide to make counting easier. All slides were stained for 20 min in 10 per cent Giemsa, decolorized through successive changes of acetone, acetone-xylene, cleared with xylene and mounted with 'Permount'. All the metaphases on each slide were counted and the number of metaphases per millilitre of suspension was calculated. In addition, relative counts of the number of metaphases per 1,000 interphases were performed.

In a second experiment, a Leffman-Beam type of centrifuge tube was used (Arthur H. Thomas, Phila., Cat. No. 2998–*G*–65) in order to test the same principle. 0·12 millilitre of a thick cell suspension of cultured leucocytes was allowed to stand vertically in the centrifuge tube for 20 min. At this time, with the aid of a siliconized, capillary pipette (Pasteur type) with a very

fine tip, the supernatant and the upper and lower portions of the sediment were sampled and slide preparations were made as above. In this case only relative counts of the number of metaphases per 1,000 interphases were performed.

Table 1. Rate of Settling of Metaphases as compared with Interphases as indicated by the Number of Metaphases per Millilitre and the Number of Metaphases per 1,000 Interphases

Tube	Sed. time (min)	Length of column (cm)	Volume (ml.)	Total No. metaphases	No. metaphases per ml.	No. metaphases per 1,000 interphases
A	0	2·0	$1·60 \times 10^{-2}$	165	10,312	20
B	5	1·5	$1·20 \times 10^{-2}$	74	6,167	24
C	10	2·8	$2·24 \times 10^{-2}$	83	3,733	20
D	15	2·1	$1·76 \times 10^{-2}$	49	2,882	18
E	20	1·8	$1·44 \times 10^{-2}$	44	3,142	19

Table 1 summarizes one set of values obtained in the first experiment and is representative of the results obtained with ten cell suspensions from different leucocyte pools.

These findings indicate that the ratio of metaphases to interphases remains essentially constant throughout the process of sedimentation. The total number of metaphases/ml. of supernatant in each capillary tube fell progressively with time. Both findings strongly suggest that cells in metaphase sediment at the same rate as cells in interphase.

Table 2. Relative Counts (Metaphases/1,000 Interphases)

Exp. No.	Supernatant	Upper level of sediment	Lower level of sediment
1	12	14	15
2	18	22	23
3	27	23	24
4	18	18	20
5	6	8	5
6	8	6	10

Table 2 shows the results of the second experiment. Since the total volume of cell suspension used for the preparation of each slide in this case was not accurately known, only relative counts were recorded. A total of six separate determinations were carried out.

These results confirm the findings of the first experiment, that is, they strongly suggest that with the methods employed no difference in the sedimentation rates of cells in interphase and cells in metaphase exists. Whether the same holds true for tumour cells in suspension was not determined.

GENETICS

Mutants of *Salmonella typhimurium* induced by 5-Bromodeoxyuridine

Freese has shown in a series of papers[1–3] that most mutants induced by 5-bromouracil or 5-bromodeoxyuridine in bacteriophage *T*4 can be induced to back-mutate by these same base analogues. This important observation led him to propose as one type of mutation the substitution of a G-C pair in the DNA for an A-T pair by a mechanism that necessarily could work in reverse. We have carried out similar experiments in the course of a study of the mutagenic action of nucleotide base analogues in *Salmonella typhimurium* and the results are somewhat different from those obtained with the bacteriophage.

Auxotrophs were induced by incubating an aerated culture of the wild type strain of *Salmonella typhimurium* known as 'LT-2' in 1 per cent 'Difco' nutrient broth supplemented with 200 μg/ml. of 5-bromodeoxyuridine, and the same concentration of aminopterin (to suppress the formation of thymine), for 18 h. After screening by the standard penicillin technique[4] 83 auxotrophs were isolated and characterized. Twenty-four were shown to be genetically different and the induction of reversions in 13 of these was examined (Table 1). These data were obtained by growing each auxotrophic strain to saturation in broth containing the base analogue and aminopterin. The bacteria were centrifuged and washed with saline before plating about 10^8 cells on each of 3 Petri dishes with enriched minimal media. The data are the average number of fast-growing colonies per plate that appear; slow-growing colonies are not included as they are unlikely to be back-mutations. Some of the fast-growing colonies also may not be back-mutations, but our experience with *Salmonella typhimurium* shows that this will probably be true of very few of them. The data on the frequency of spontaneous mutants were obtained similarly; the broth cultures contained no base analogue or aminopterin and the bacteria were plated when the population of cells had reached the same density as that of the saturated cultures with the base analogues.

Reconstruction experiments showed that prototrophic cells were not at a selective advantage or disadvantage in the media with or without base analogues. We were also able to show, by sampling the broth cultures at different times, that in the presence of bromouracil and aminopterin the induction of mutations occurred mainly in the last two cell generations of the culture whereas with bromodeoxyuridine and aminopterin the induction started somewhat earlier. Aminopterin without a base analogue does not induce mutations. Bromouracil and bromodeoxyuridine, but not aminopurine, require aminopterin to become mutagenic.

Table 1. Frequencies of Fast-growing Reversions of 13 5-bromodeoxyuridine-induced Auxotrophs of *Salmonella typhimurium* in the Presence of 2-aminopurine (AP), 5-bromouracil (BU), 5-bromodeoxyuridine and in the Absence of any Base Analogues (C). (The Range indicates Extreme Frequencies in 2 or more Repeat Experiments)

gua-15	0·0	0·0–19·0	0·0	0·0–0·3
nic-7	0·0	0·0	0·0	0·0

From Table 1 the order of decreasing effectiveness of the base analogues is bromodeoxyuridine, bromouracil and aminopurine on mutants *cys*-1055, *cys*-1056, *ser*-703, *ser*-704, *ser*-705 and possibly *pyr*-190. This was the most common order of effectiveness found on 9 spontaneous and 18 aminopurine-induced mutants. Omitting the completely stable *nic*-7 auxotroph all the remaining 6 mutants were most sensitive to aminopurine while they responded little, if at all, to the pyrimidine analogues; a relative effectiveness that we have not found in any spontaneous or aminopurine-induced mutant. Four of the 6 gave even higher frequencies of reversions with aminopurine when thymine, and to a lesser extent adenine, was added to the broth. Although the reversion of some of the other 5-bromodeoxyuridine-induced auxotrophs by aminopurine was also enhanced by thymine this effect was absent in all of four spontaneous and five aminopurine-induced mutants that were tested.

It appears that, in *Salmonella typhimurium*, bromodeoxyuridine induces mainly two types of mutation

which are distinguishable by their sensitivity to aminopurine on one hand, and to bromodeoxyuridine and bromouracil on the other, in inducing back-mutations. One type can be reverted more readily by the pyrimidine analogues than by aminopurine. The other type responds poorly, if at all, to the pyrimidine analogues but responds well to aminopurine; the effectiveness of aminopurine on most of these mutants is enhanced by thymine. We have not found this second class among spontaneous or aminopurine-induced mutants; it appears to be one of the two main classes among bromodeoxyuridine-induced mutants. As it is induced by a base analogue it is likely to be a base-pair change—a change that cannot be readily reverted by the base analogue that induced it.

It seems from this and other work that the pattern of induction and reversion of mutations in *Salmonella typhimurium* is more complex than the patterns described in bacteriophage.

SOIL SCIENCE

Resistance of Tea Plants to Blister Blight in Soils augmented with Nickel

In 1961, protective spraying of tea plants with nickel chloride hexahydrate gave dramatic control of the blister blight disease[1], and later certain salts of nickel were shown to possess eradicative control properties when applied in a dilute aqueous solution to tea foliage 3–5 days after inoculation with *Exobasidium vexans* Massee, the causal pathogen[2]. Very recently it has been observed that, in soils augmented with nickel ammonium sulphate and nickel nitrate, tea plants developed disease resistance.

Potted tea plants of susceptible monoclonal selection, 12 months from cutting, were pruned back to 6 in., incubated in a plastic house and used for the experiment when they had produced 3–4 shoots. The 5 lb. of soil in each pot was treated with 1, 2 or 3 g of nickel ammonium sulphate, applied on the surface and watered down, untreated controls being maintained. The young leaves in four plants in each treatment, and the control, were artificially inoculated with spores of *E. vexans* by the usual method[2], 5, 8, 15 or 20 days after the nickel was applied to the soil. After inoculation the plants were incubated at room temperature (20°–30° C), protected against natural infection from air-borne spores. Observations were made on the number of lesions that developed, and the number of sporulating blisters, up to 14 and 21 days, respectively, after inoculation.

Results (Table 1) showed that the number of lesions developing on plants in soil treated with nickel ammonium sulphate 5 days before inoculation was markedly lower when compared with the control. In the lots inoculated 8, 15 and 20 days after treatment, no lesions formed on plants treated with nickel ammonium sulphate at 3 g/pot; at the lower dosage of 2 and 1 g the plants developed only a few lesions whereas control plants were heavily infected. Similar results were obtained when nickel nitrate was used. No specific influence of nickel application on sporulation was noticed; lesions which formed on treated plants sporulated in the same proportion as those in the untreated ones. Symptoms of iron chlorosis developed in the second week in the treated plants and growth was slightly retarded.

Table 1

Nickel ammonium sulphate treatment	Number of lesions on 4 plants maintained for 5, 8, 15 and 20 days in treated soil							
	5		8		15		20	
1 g/pot	87 (10)	**52***	14 (12)	**14**	5 (14)	**4**	23 (13)	**19**
2 g/pot	126 (19)	**91**	33 (10)	**22**	2 (12)	**2**	8 (11)	**6**
3 g/pot	44 (18)	**30**	0 (13)		0 (18)		0 (14)	
Control	261 (13)	**225**	201 (14)	**180**	141 (14)	**114**	256 (14)	**219**

* Figures in parentheses give the number of leaves examined, those in bold type the number of lesions which sporulated.

In preliminary experiments in the field, when 4-year-old clonal plants were each given 4, 8 and 12 g nickel ammonium sulphate, dibbered into the soil around the collar and watered down, they seemed to develop resistance to blister blight for 4 weeks following treatment, but mature bushes which received 15 g showed no such resistance. No increase in nickel level was observed in the leaf from these mature bushes when analysed by dry ashing polarographic technique 2, 3 and 4 weeks after soil treatment. Symptoms of iron chlorosis were not seen in either the 4-year-old clonal plants, or the mature bushes, at these rates of nickel application. Leaves from different clones growing in the same locality were analysed, when it was seen that one which is immune to blister blight contained 14–25 p.p.m. nickel, as opposed to 6–10 p.p.m. in two susceptible clones, indicating that in tea plants nickel may have an important role in host resistance to blister blight.

Help from the International Nickel Company (Mond), Ltd., London, in the analysis of leaf samples for nickel content is gratefully acknowledged.

Simple Estimation of Soluble Salts in Glasshouse Soils

For a number of years the National Agricultural Advisory Service has been carrying out routine determinations of electrical conductivity on aqueous extracts of glass-house soils as an advisory service to horticulturists. Extracts are usually prepared at a water : soil ratio of 2·5 : 1 by shaking 16 g of soil with distilled water for 15 min. After settling, conductivity determinations on the clear extract are carried out at a temperature of 20° C and the results are usually expressed as pC or Cf values, pC being the negative logarithm of the specific conductivity and Cf being the specific conductivity multiplied by 10^4. These values have been classified on the basis of soluble salt content of soils and effect on plant growth[2], and are often used to predict harmful effects to plants due to accumulation of fertilizer residues.

It has been recognized for some time that the interpretation of pC values has certain difficulties caused by the properties of calcium sulphate which tends to accumulate in glasshouse soils where sulphate fertilizers are used or where the water is hard. Calcium sulphate cannot reach a high concentration in the soil solution owing to its low solubility, and it has been shown by experimental work (ref. 3, confirmed in this laboratory) that calcium sulphate is harmless to lettuce and tomato plants even when present in large excess. It can, however, greatly affect laboratory measurements of conductivity when carried out at a high solvent : soil ratio[4,5] for convenience in routine analysis. This is because at a high solvent : soil ratio much more calcium sulphate can dissolve, if a considerable amount is present in the soil, than would be in solution when plants were growing in the soil.

Winsor *et al.*[3] found that the difficulties due to calcium sulphate could be eliminated simply by determining the conductivity in a soil extract obtained by using saturated calcium sulphate solution instead of water[5], thereby eliminating calcium sulphate as a variable in the extract.

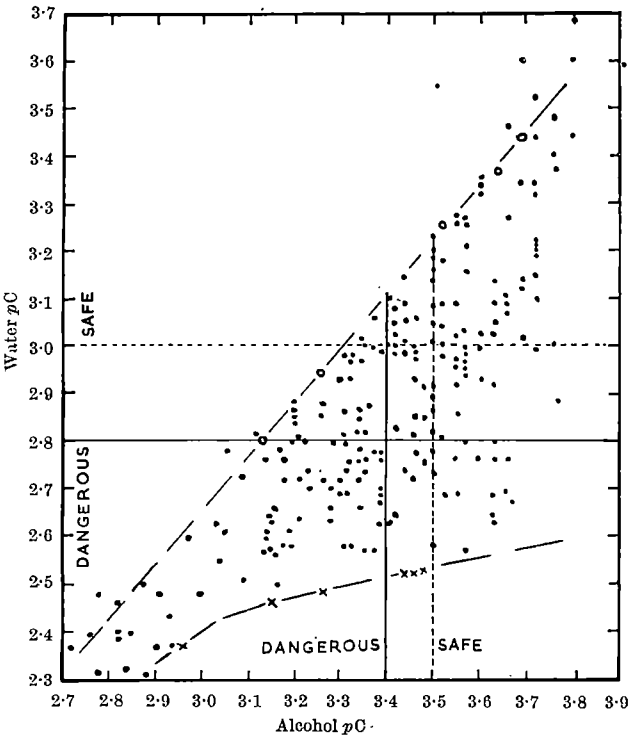

Fig. 1. The relation between *p*C readings, determined in water and in 25 per cent alcohol saturated with calcium sulphate, of soils with various calcium sulphate contents. ○ Soils known to contain no more than a trace of calcium sulphate. ● Routine 'advisory' soils. × Experimental soils to which excess calcium sulphate has been added

They pointed out, however, that the range of conductivity is restricted in this way and measurements must be precise. As the conductivity due to harmful salts will nearly always be much less than the conductivity due to calcium sulphate, when this is present in excess, small analytical errors may be important. In this paper a method is described which overcomes the difficulties due to calcium sulphate without restricting the range of values obtained.

Water–alcohol mixtures for preparation of extracts. The solubility of calcium sulphate in water (0·22 g/100 ml. at 20° C) was found to decrease sharply when ethyl alcohol was added until at 25 per cent by volume the solubility was reduced to approximately 0·01 g/100 ml. Further addition of alcohol had little effect, so the use of 25 per cent alcohol instead of water appeared to be a possible way of minimizing the effects of calcium sulphate on *p*C readings.

Salts which commonly occur in glasshouse soils were found to be sufficiently soluble in 25 per cent alcohol for complete solution of the amounts likely to be present to take place at a solvent : soil ratio of 2·5 : 1. The ratio of conductivity in 25 per cent alcohol to that in water was 0·5 for all salts tested except for magnesium sulphate for which the ratio was 0·4.

In 1961, 25 per cent alcohol, saturated with calcium sulphate to eliminate this salt as a variable, was introduced as an additional solvent for *p*C determinations in the West Midland Region of the N.A.A.S. Apart from the change of solvent the technique used was identical to the water *p*C method. As the solubility of calcium sulphate in 25 per cent alcohol is very small, the conductivity due to calcium sulphate is much less than that due to the highly soluble salts present, except in soils containing very small amounts of the latter.

The relation between water and alcohol pC readings. Since 1961 a considerable amount of information has accumulated on the relation between *p*C determinations on routine advisory soils from commercial glasshouses in the West Midlands using water and 25 per cent alcohol saturated with calcium sulphate as solvents. These data are summarized in Fig. 1, which also includes some data from soils known to contain no more than a trace, and some containing an excess, of calcium sulphate. The calibrations of the water *p*C method used in the West Midland Region before 1961, and of the alcohol *p*C method described here, are shown.

In Fig. 1 almost all the points from routine soils lie within the area bounded by broken lines through the points representing soils free of calcium sulphate and soils with excess calcium sulphate. Thus it is evident that the calcium sulphate content of soils from commercial glasshouses varies from no more than a trace to sufficient to saturate the water extract obtained at a solvent : soil ratio of 2·5 : 1.

The use of alcohol pC readings in advisory work. Since the introduction of the alcohol *p*C method, experience has shown that the readings obtained reflect the harmful effects of excessive fertilizer on plant growth. A tentative calibration of the method was obtained from experimental work on tomato plants and chrysanthemums. On the basis of this experimental work and advisory experience, alcohol *p*C values are at present classified as follows:

3·50 and above — safe
3·40–3·49 — doubtful
3·39 and below — dangerous

The alcohol *p*C method overcomes the difficulties due to the presence of calcium sulphate in the soil in a simple way and is suitable for routine laboratory work. Interpretation of the values obtained will be affected to some extent by variations of moisture-holding capacity, with texture and organic-matter content, as the determinations are made on a constant weight of soil. However, the calibration reported here has been found to be generally applicable in the West Midlands. It should be possible to make a more detailed calibration for different plants when further experimental work has been done.

I am indebted to Mr. G. H. A. Edwards, who initiated the investigation on the effects of calcium sulphate on plant growth and *p*C values, and to Mr. A. J. Cavell, who suggested the use of ethyl alcohol to minimize the solubility of calcium sulphate and supervised the laboratory work.

Quantitative Analysis of Clay Mineral Mixtures by X-ray Diffraction

The basic relation underlying all quantitative diffraction analyses with the X-ray diffractometer is[1]:

$$I_1 = \frac{K_1 X_1}{\rho_1 (X_1(\mu_1^* - \mu_M^*) + \mu_M^*)} \quad (1)$$

From this it can be established mathematically that[2]:

$$\frac{I_A}{I_B} = \frac{K_A X_A \rho_B}{K_B X_B \rho_A} \quad (2)$$

where I_A and I_B represent peak intensities, K_A and K_B specific mineral constants, X_A and X_B the weight fractions and ρ_A and ρ_B the densities of components A and B in a diffracting mixture. This relationship holds whatever the amount or number of components. In equation (2) K_A, K_B, ρ_A, ρ_B are constants for minerals A and B. The equation thus reduces to the linear relationship:

$$\frac{I_A}{I_B} = \omega \times \frac{X_A}{X_B} \quad (3)$$

where I_A/I_B is independent of specific mineral as well as of matrix mass absorption coefficients (μ_A^*, μ_B^* and μ_M^*).

If the value of ω for mixtures of two diffracting components can be established by observations on mixtures containing these two components in known proportions, then the relative fractions of these two components in a mixture of unknown composition can readily be determined. Likewise, in a mixture of more than two diffracting components, the weight fractions of components in pairs can be estimated and, hence, using the relation:

$$X_A + X_B \ldots X_N = 1 \qquad (4)$$

an estimate of each weight fraction of each constituent can be obtained. Thus a simple procedure for the quantitative estimation of diffracting constituents in clay mixtures and other materials becomes available.

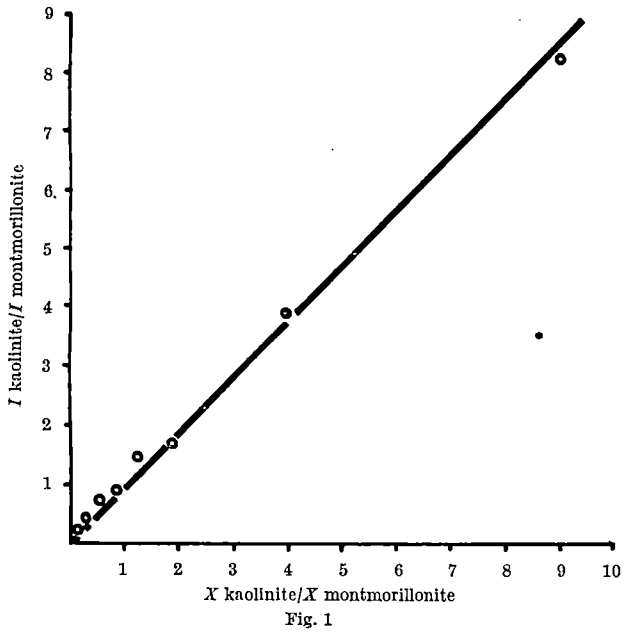

Fig. 1

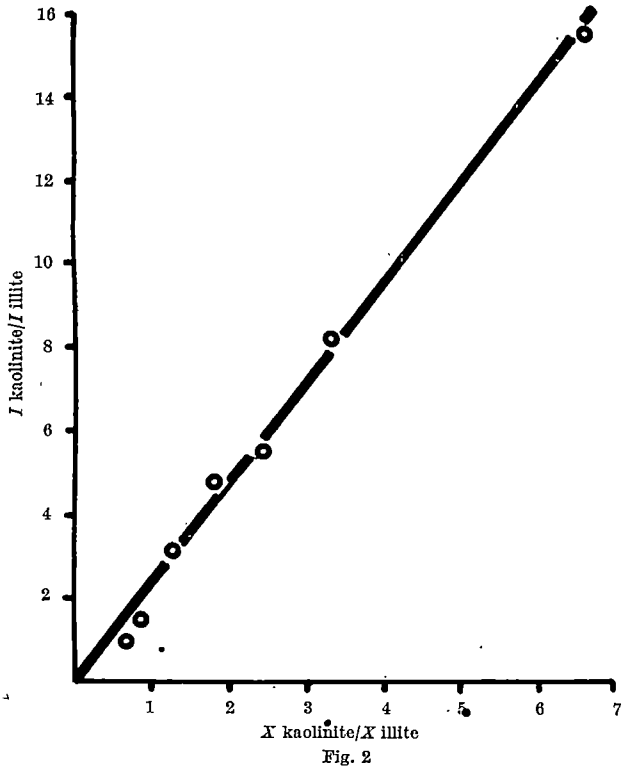

Fig. 2

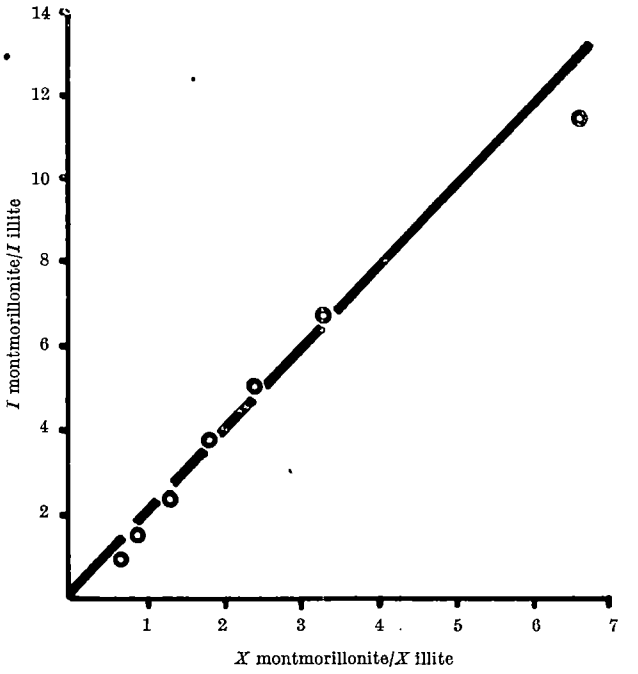

Fig. 3

The validity of relationship (3), and hence the validity of the estimation procedure based on it, has been confirmed for binary mixtures of kaolinite and montmorillonite, montmorillonite and illite, and kaolinite and illite, respectively, using type specimens of these minerals obtained from Wards Natural Science Establishment Inc., Rochester, New York. The samples were prepared for diffractometry by spreading small quantities of magnesium-saturated 2–0·2μ clay from the deposit at the bottom of a centrifuge tube evenly with unidirectional strokes on to petrographic microscope slides[3]. After air- and oven-drying, each sample was examined with a Philips direct-recording X-ray diffractometer, using copper $K\alpha$ radiation. Measurements of first order peak intensities were obtained by a 'fixed time' counting method. The linear relationship between I_A/I_B and X_A/X_B for each of the three mixtures is shown in Figs. 1–3.

Furthermore, the method was tested for mixtures containing three components. Using the straight-line relationships illustrated in Figs. 1–3, 15 different ternary mixtures were estimated by considering the intensity ratios of the kaolinite, montmorillonite and illite components in pairs. The final estimates, together with the actual compositions, are illustrated in Table 1. Nine of the 15 samples were estimated with an accuracy of ±3 per cent or better, 13 with an accuracy of ±4 per cent or better, and all 15 with an accuracy of ±4·5 per cent or better. If mixtures of extreme composition (10 per cent or less) of montmorillonite, illite and kaolinite are separated from those of

Table 1

Sample No.	Actual composition: Montmorillonite	Illite	Kaolinite	Estimated composition: Montmorillonite	Illite	Kaolinite	Deviation
3	83·0	6·5	10·5	78·5	10·0	11·5	4·5
1	78·0	16·5	5·5	75·0	17·5	7·5	3·0

				Total deviation			44·5
				Average deviation			2·97

more balanced composition, the average deviation of the latter is reduced to ±2·33 per cent.

Where an accuracy of ±10 per cent is adequate, on the basis of equation (1), the K constants for the individual minerals can be estimated using peak intensities of type specimens. The lower accuracy of this direct calculation procedure arises from the inherent inaccuracies attached to the estimation of specific mineral density and of mass absorption coefficients.

FORESTRY

Field Technique for the Concentration of Rainfall within the Individual Seedling Root Range

Forestry nursery practice provides young seedlings, particularly during the critical period following germination, with conditions in which the necessary protection and adequate soil moisture are ensured. In the field, direct seeding in partially buried bamboo sleeves will ameliorate the seedling environment. However, under field conditions it is not feasible to augment soil moisture by watering, and the plant is therefore dependent on rainfall, which in many cases is unreliable and insufficient. Recent work by Glover and Gwynne[1] has demonstrated that the interception of rain by the aerial parts of established plants can concentrate otherwise ineffectual light showers of rain into useful quantities of water within the root range of the plant. An experiment on the direct seeding of three commonly grown exotic species *Pinus radiata*, *P. patula* and *Cupressus lusitanica* at Muguga, Kenya (1° S., 37° E., altitude 6,800 ft.), has shown that a rainfall conductor stick implanted in the soil adjacent to the sown seed increases the seedling survival rate, when used in conjunction with the bamboo sleeve technique (which will be described elsewhere).

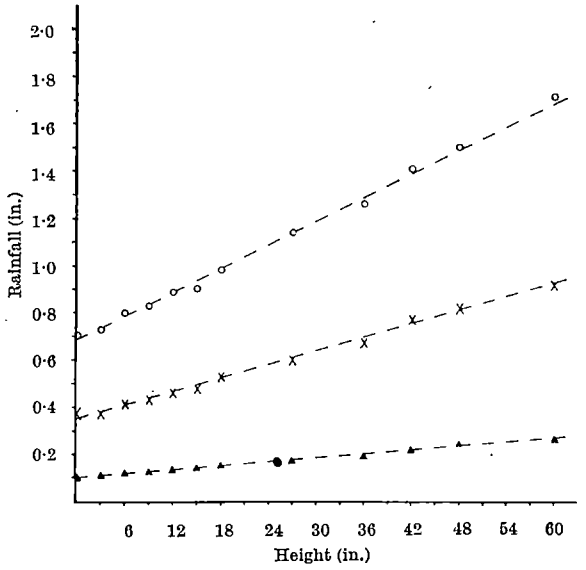

Fig. 1. The mean increase for 1-in. conductors, classified by three storm sizes. ○, rainfall class 0·50–1·00; ×, rainfall class 0·25–0·50; ▲, rainfall class 0·00–0·25

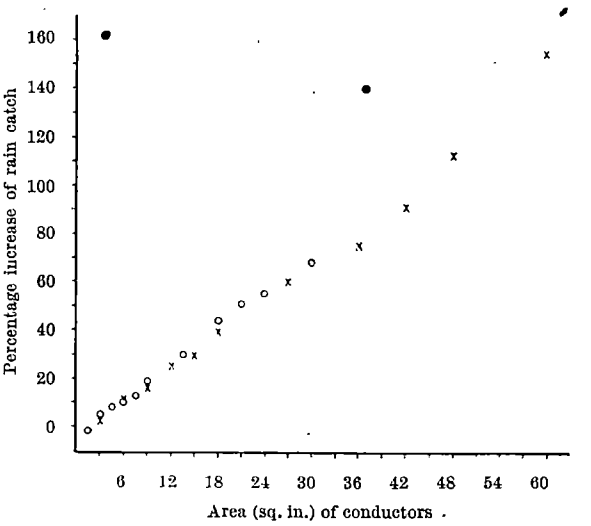

Fig. 2. Percentage increase of rainfall catch by conductors for all storms

To measure the catchment effect of these conductors, bamboo splits, 1 in. wide and 3 in. to 60 in. long, were mounted vertically in standard Snowdon-type rain-gauges and placed in line at right angles to the prevailing wind, with a similar gauge used as the control. After the first rainy season these conductor sticks were halved in area by reducing their width to 0·5 in. The daily rainfall catch was measured for two rainy seasons in 1963; it totalled 17 in. in 46 wet days and 13 in. in 43 wet days respectively. The rainfall pattern was similar for both seasons, with about half of the total rainfall in each period occurring as light showers of less than 0·25 in. These light showers would, under the evaporation conditions obtaining at Muguga, contribute little or nothing to the soil moisture build-up[2]. The measured mean daily wind speed at the site ranged from 5–9 m.p.h., and as few rainstorms were accompanied by strong winds the angle of rainfall for the vast majority of the storms was near the vertical.

The mean daily rainfall totals during the first season, when the 1-in. conductor sticks were in operation, have been classified by storm size into three groups as shown in Fig. 1; the efficiency of the conductor is maintained in all three classes. Fig. 2 illustrates the effect of surface area on rainfall catch for both widths of stick measured over the two rainy seasons. Both figures show that for each class of rainfall the gain in water is consistently proportional to the surface area of the conductor sticks. A depression of the order of 2 per cent occurred in all catches due to the reduction in receiving area of the rain-gauge consequent on the installation of the bamboo sticks; this cancelled out the gain in rainfall from the 0·5 in. × 3 in. stick, but for larger conductors the effect was negligible compared with the increased rain catch. A conductor stick of practical size for field work, say, 30 sq. in., will increase the quantity of water arriving at the base of the stick by more than 60 per cent. Thus, rainfall conductor sticks effectively increase the soil moisture within a given area and thereby enhance the conditions for plant survival and growth. In areas where the daily loss by evaporation is high, the conductors can turn ineffectual light showers into beneficial concentrations of water.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

EXPERIMENTAL OFFICER (with a degree or diploma in chemistry and appropriate experience) IN THE CHEMISTRY DEPARTMENT, for handling and analysis of crop and soil samples and to develop analytical methods for nitrogen—The Secretary, Rothamsted Experimental Station, Harpenden, Hertfordshire (December 24).

LECTURER IN CHEMISTRY to teach in O.N.C. and G.C.E. "A" level courses and to assist in the organization of the Science Department; and an ASSISTANT LECTURER, Grade B, FOR BIOLOGY, to teach G.C.E. "O" and "A" level biology mainly to full-time courses—The Principal, North-East Essex Technical College and School of Art, Sheepen Road, Colchester, Essex (December 26).

ADMINISTRATIVE SECRETARY (man or woman, with administrative experience, and preferably a degree or qualification in geography or education) to take general charge of the headquarters in Sheffield—The Honorary Secretary, The Geographical Association, 343 Fulwood Road, Sheffield, 10 (December 30).

ENTOMOLOGIST to the Citrus Research Unit, University of the West Indies, Kingston, Jamaica—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (December 30).

LECTURER or ASSISTANT LECTURER IN LOGIC AND METAPHYSICS; and a LECTURER or ASSISTANT LECTURER IN MORAL PHILOSOPHY—The Secretary, The University, Aberdeen (December 30).

D.S.I.R. RESEARCH ASSISTANT (honours graduate in engineering or physics) IN THE DEPARTMENT OF MECHANICAL ENGINEERING, to carry out investigations in the field of electrostatic precipitation—Prof. H. E. Rose, King's College (University of London), Strand, London, W.C.2 (December 31).

LECTURER or ASSISTANT LECTURER IN THE SCHOOL OF BIOLOGICAL SCIENCES—The Registrar, University of East Anglia, Earlham Hall, Norwich, NOR 05G (December 31).

LECTURER or ASSISTANT LECTURER (or, exceptionally, Senior Lecturer) IN SOCIOLOGY—The Assistant Registrar, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (December 31).

LECTURER (with an honours degree with specialization in modern algebra or analysis, and three years teaching experience, preferably at university level) IN MATHEMATICS at the University of Nigeria, Nsukka, Eastern Nigeria—The London Representative, University of Nigeria, 33 Craven Terrace, London, W.2 (December 31).

SENIOR LECTURER (with high academic qualifications and relevant teaching or industrial or research experience) IN MAMMALIAN PHYSIOLOGY IN THE DEPARTMENT OF BIOLOGICAL STUDIES—The Principal, Lanchester College of Technology, Priory Street, Coventry (December 31).

SENIOR LECTURERS, LECTURERS or ASSISTANT LECTURERS IN MATHEMATICS—The Secretary, University of Lancaster, Bailrigg House, Lancaster (December 31).

CHAIR OF PHYSICS—The Registrar and Secretary, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (January 1).

UNIVERSITY LECTURER IN SOIL SCIENCE—The Secretary of Faculties, University Registry, Oxford (January 1).

LECTURER IN CLINICAL PSYCHOLOGY IN THE DEPARTMENT OF PSYCHOLOGICAL MEDICINE—The Secretary of the University Court, The University, Glasgow (January 4).

LECTURERS (3) (with a degree in physiology, biochemistry, pharmacology, chemistry, medicine or zoology and postgraduate research experience of Ph.D. or equivalent standard) IN PHYSIOLOGY or BIOCHEMISTRY—The Deputy Secretary, The University, Southampton (January 8).

SENIOR LIBRARY ASSISTANTS (2), one to take charge of the Library of the Faculty of Agriculture, and one for duties in the David Keir Science Library—The Secretary, The University, Belfast, Northern Ireland (January 8).

ENGINEER or PHYSICIST (with a good honours degree in engineering or physics and either research experience of Ph.D. standard or good practical civil engineering experience) IN THE BUILDING SCIENCE LABORATORIES, to work under the direction of Dr. G. H. Tattersall, on work connected with industrialized building and compaction of concrete by vibration—The Registrar, The University, Sheffield (January 9).

LECTURER or ASSISTANT LECTURER IN MATHEMATICAL STATISTICS, to work with an existing group of five members of staff—The Registrar, The University, Manchester, 13 (January 9).

LECTURER (preferably with main interests in the field of inorganic or theoretical chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Assistant Registrar (Science), The University of Birmingham, Birmingham, 15 (January 11).

UNIVERSITY LECTURER IN GEOCHEMISTRY IN THE DEPARTMENT OF GEOLOGY AND MINERALOGY—The Professor of Geology, Department of Geology and Mineralogy, University Museum, Oxford (January 11).

ASSISTANT LECTURER IN PHYSIOLOGY at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, January 15).

ASSISTANT LECTURERS (3) IN PHILOSOPHY—The Registrar, Room (T), The University, Hull (January 15).

CHAIR OF CROP HUSBANDRY AND HORTICULTURE at the University of Ghana—The Assistant Registrar, University of Ghana Overseas Office, 15 Gordon Square, London, W.C.1; or The Registrar, University of Ghana, P.O. Box 25, Legon, Accra, Ghana (January 15).

LECTURER IN ENGINEERING SCIENCE—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (January 15).

LECTURERS or ASSISTANT LECTURERS (with a recognized honours degree in civil, mechanical or electrical engineering, experience in research, and preferably practical experience and experience of teaching at degree level) IN THE DEPARTMENT OF ENGINEERING, University of Malaya—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Kuala Lumpur and London, January 15).

SENIOR LECTURER IN THE DEPARTMENT OF ANATOMY at the University of the Witwatersrand, Johannesburg, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, January 15).

SENIOR LECTURER or LECTURER IN THE DEPARTMENT OF ZOOLOGY, University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 15).

SENIOR LECTURER or LECTURER (qualified veterinarian with postgraduate clinical teaching and research experience) IN THE DEPARTMENT OF VETERINARY MEDICINE, TOXICOLOGY AND THERAPEUTICS, at the University of Khartoum—The Registrar, University of Khartoum, c/o The Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 15).

SENIOR TECHNICIAN or TECHNICIAN IN THE DEPARTMENT OF BIOCHEMISTRY AND SOIL SCIENCE, University of Khartoum—The Registrar, University of Khartoum, c/o Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 15).

LECTURER IN PHILOSOPHY—The College Secretary, Balliol College, Oxford (January 16).

ASSISTANT RESEARCH FELLOW IN SOCIOLOGY, ANTHROPOLOGY or SOCIAL PSYCHOLOGY at Makerere University College, Uganda—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 20).

LECTURER IN PSYCHOLOGY at the University of Cape Town—The Secretary-General, Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1; and The Registrar, University of Cape Town, Private Bag, Rondebosch, Cape Town, South Africa (January 20).

READER IN EXTRACTION METALLURGY at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 20).

LECTURER (with an honours degree in pharmacy, and preferably Registered Pharmacist with a higher degree and teaching or industrial experience) IN PHARMACY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, January 22).

SENIOR LECTURER or LECTURER IN APPLIED MATHEMATICS—The Registrar, Room (T), The University, Hull (January 26).

LECTURER or ASSISTANT LECTURER (with interests in soil mechanics) IN ENGINEERING—The Registrar, The University, Manchester, 13 (January 30).

LECTURER (preferably interested in numerical analysis or a related field) IN PURE MATHEMATICS in the Faculty of Science—The Registrar, The University, Manchester, 13 (January 30).

RESEARCH FELLOW IN MATHEMATICS—The Secretary of the University Court, The University, Glasgow (January 30).

TUTORIAL FELLOW IN BIOCHEMISTRY—The Senior Tutor, University College, Oxford (January 30).

UNIVERSITY LECTURER IN BIOCHEMISTRY—Professor Sir Hans Krebs, F.R.S., Department of Biochemistry, South Parks Road, Oxford (January 30).

AGRICULTURAL ENGINEER (with a degree in agricultural engineering or mechanical engineering with postgraduate qualifications in agricultural engineering, and some practical experience) in Mauritius, to design or modify machinery and equipment for agricultural use in the Colony, to design and install pilot mechanical plants relating to indigenous agricultural development and for general consulting and engineering work—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting Ref. RC 213/111/01.

AGRICULTURAL OFFICERS (national of the United Kingdom or the Republic of Ireland, with a degree in agriculture or natural science, plus at least two years experience of tropical agriculture) in Sarawak, for the administration of an Agricultural Division, comprehensive advisory and supervisory duties and supervision of experiment stations and staff training—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting RC 213/155/04.

ASSISTANT LECTURER (with a good honours degree in biology or zoology) IN BIOLOGY—The Registrar, University of Strathclyde, George Street, Glasgow, C.1.

CHAIR OF PHYSIOLOGY—The Registrar and Secretary, The University, Bristol.

LECTURER IN OPERATIONAL RESEARCH AND APPLIED STATISTICS—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 27/G.

LECTURER IN THE DEPARTMENT OF PHYSICS, University of the Witwatersrand, Johannesburg, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

LECTURERS or SENIOR LECTURERS (with a first- or second-class honours degree or equivalent) IN PHYSICS—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wilts.

MASTER to take charge of Biology; and a CHEMISTRY MASTER to teach up to G.C.E. "A" level and scholarship—The Rector, The Edinburgh Academy, Edinburgh, 3.

PHYSICISTS and PHYSICAL CHEMISTS (preferably with a minimum of three years research experience) to work on various problems in the fields of membrane permeation, polymer structure and its relation to electrical behaviour; and ORGANIC CHEMISTS to work on interesting problems in the carbohydrate field in connexion with the utilization of natural products—The Director, Arthur D. Little Research Institute, Inveresk, Musselburgh, Midlothian, Scotland.

PHYSICS TECHNICIAN (with G.C.E. "A" levels in mathematics or physics), or a RADIOGRAPHER IN THE RADIOTHERAPY DEPARTMENT for work on clinical application of isotope techniques—The Assistant Secretary, University College Hospital, Gower Street, London, W.C.1.

PLANT PHYSIOLOGIST (national of the United Kingdom or the Republic of Ireland, with a good second-class honours degree in botany, with particular emphasis on physiology, ecology, and preferably postgraduate experience in plant physiology research, with particular reference to water shortage on plant growths) with the East African Common Services Organization, to carry out research on agreed problems in the physiology of root development and growth in some East African economic plants, with particular reference to the effects of water stress—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting RC 213/214/010.

RESEARCH ASSISTANT (with an honours degree or a Diploma in Technology, and preferably some familiarity with semi-conductor circuits, optics or the design of small instruments) IN THE DEPARTMENT OF MATHEMATICS for daylight star detection—The Secretary and Registrar, Bristol College of Science and Technology, Ashley Down, Bristol, 7, quoting Ref. CST 64/111.

RESEARCH FELLOW (with the degree of Ph.D. or about to submit a Ph.D. thesis in organic chemistry) IN THE DEPARTMENT OF CHEMISTRY for an investigation concerned with the synthesis of heterocyclic compounds of potential therapeutic interest—The Professor of Chemistry, Room (T), The University, Hull.

SENIOR LABORATORY TECHNICIAN (with specialized skill in either botany or zoology and a general familiarity with the techniques in the other subject for supervision purposes) IN THE DEPARTMENT OF BOTANY AND ZOOLOGY—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

SENIOR TECHNICIAN (with extensive experience of machine tools) to assist in construction of a vacuum system, magnets and associated equipment for a 15 MeV Linear Accelerator—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

TEACHING and RESEARCH ASSISTANTSHIPS leading to M.Sc. and Ph.D. degrees—Head, Department of Biochemistry, University of Alberta, Edmonton, Alberta, Canada.

DISARMAMENT AND THE ROLE OF THE SCIENTIST

IN his Essex Hall Lecture, "Scientists' Responsibility in the Atomic Age" (now published*), Prof. J. Rotblat urges that progress in science and technology has not been matched by corresponding progress in problems of relations between communities and nations, or in strengthening moral principles and adhering to standards of ethics, and claims that this divergence can be expressed quantitatively. While the growth of scientific and technological activities has a doubling time of about ten years, corresponding to an annual growth of about 7 per cent, for non-scientific activities the doubling time is about forty years, with an annual rate of growth roughly proportional to that of the world's population. This divergence is dangerous because of the immense destructive potentialities of the new powers if they are misused. The danger is the greater because of the lack of progress in international relations, the neglect of moral ideals and the prevalent disregard for the value and sanctity of human life.

Prof. Rotblat considers that the most immediate danger arises from the presence of large stockpiles of nuclear weapons, which increase in size exponentially as the delivery time of such weapons is continually shortened. He is sceptical as to the real deterrent value of such weapons and comments on the depressing effect that such a situation has on moral values, especially among the younger generation. The Commonwealth Prime Ministers in 1961 accepted the need for a disarmament agreement, the aim of which must be to achieve total world-wide disarmament subject to effective inspection and control; and in view of the slaughter and destruction experienced in so-called 'conventional' wars and the difficulty of preventing such a war, once started, from developing into a nuclear war, our aim must be nothing less than the abolition of the means of war of any kind. Similar ideas have been expressed by the leaders of Governments of the United States and the U.S.S.R., but so far the only worth-while achievement has been the agreement signed in Moscow in 1963 between the United Kingdom, the United States and the U.S.S.R. to cease tests of nuclear weapons in the air, under water and in the upper regions of the atmosphere.

While this will mean the end to further poisoning of the atmosphere with radioactive materials from fall-out, Prof. Rotblat points out that this is not enough, and, since his lecture was delivered, his warning has been substantiated by the French and Chinese nuclear tests. Indeed, he visualizes new and much more simplified means of wholesale destruction becoming accessible even to small and less-developed nations, and maintains that the world will not be a safe place to live in so long as mistrust exists between the nations. One cause of this mistrust is the enormous disparity in the standards of living, which is increasing rather than decreasing, and while Prof. Rotblat recognizes that aid to the underdeveloped countries could be expanded and organized to diminish this danger, he does not think that this alone will suffice. An entirely new approach is needed to the fundamental problems of society.

First, Prof. Rotblat insists once again that the change resulting from the advance of science and technology necessitates a radical change in our attitudes to major issues. Ultimately a world authority must be established, but this is a long way ahead and in the meantime it is no longer tolerable that international disputes should be settled by force. If we are to survive we must develop a community of interest for all mankind, irrespective of national boundaries or differences in economic or political systems.

This is largely common ground, differences of opinion lying rather in the means by which progress is to be achieved. Prof. Rotblat points out, moreover, that to achieve our purpose we must change completely the aims of education. Without abandoning loyalties to the national heritage we must emphasize the permanent community of interest of mankind and seek to develop a sense of responsibility for mankind as a whole. Admittedly, this is a long-term process and some effective measures are required immediately. For these Prof. Rotblat looks especially to the scientist who, besides sharing the common duty of mankind, has more specific obligations.

Before discussing this special role, Prof. Rotblat refers to the responsibility of both public and Government as expressed by the Atomic Scientists' Association. The right use of science is a joint responsibility of scientists, governments and public; and abuse arises from the neglect of this shared responsibility. Clear recognition by any government of its own responsibilities—including that of ensuring full freedom of discussion as well as of investigation by the scientists—and public understanding of the implications, will go far to create better understanding between public and scientists, as well as more effective utilization of scientific results.

The scientist, however, must recognize that science is a natural, if not the best, medium for fostering international understanding, as well as a most important force in the development of society. Moreover, it can make vital contributions to the solution of social and political problems, and the Pugwash Movement is one of the most important ways in which scientists themselves have sought in recent years to fulfil their social obligations. From the outset the Movement gave high priority to the problem of disarmament, of finding means of halting the arms race and destroying the stockpile of weapons, and the measures emphasized at its first conference in July 1957 still hold. These include the lessening of tensions among nations and the promotion of mutual understanding among their peoples; the ending of the arms race; the provision of reasonable safeguards in the arms control system to give substantial protection and to build up mutual confidence; the negotiation of a step-by-step process to develop as satisfactory a set of controls and safeguards as practicable.

The Pugwash Conferences have become established as an important and effective channel of communication between East and West for constructive thought and the pursuit of peace. They have demonstrated the practicability of successful international debate on controversial issues, and conferences of this type may well play an

* *Scientists' Responsibility in the Atomic Age* (The Essex Hall Lecture, 1964). By Prof. J. Rotblat. Pp. 28. (London: The Lindsey Press.) 2s. 6d.

increasingly important part in world affairs. Prof. Rotblat does not, however, indicate exactly how the way forward lies, but seems to suggest that some more formal organization may be desirable with perhaps the institution of an international council of scientists to keep the political situation continually under review. On that there may well be two opinions, particularly if the further development of the social sciences leads to the establishment of an international union in that field.

What is clear is that the position offers a great challenge to clear and constructive thinking. When Earl Russell addressed a meeting organized by the Bertrand Russell Peace Foundation in Manchester in April he expressed the opinion that the task had very largely been accomplished of inculcating on Governments and peoples the calamitous nature of nuclear war, and went on to suggest that the time had come for a new approach. He believed that one of the most urgent tasks was to devise some scheme of disarmament to which both the United States and U.S.S.R. could agree.

Earl Russell is also among the signatories to a statement addressed in July to scientists and engineers in Great Britain which urged that the social responsibility of engineers and scientists was to concentrate their energies on the exploration and development of the world's resources to meet the problems of peace, and, secondly, to impress on their colleagues or students, when seeking a job, that there are as many opportunities for constructive as for potentially destructive work, even though the latter may be better paid. The statement urges that a real way to peace would be to divert much of the money now being spent on armaments to agricultural research and education and the equipment needed to make them effective. In Britain much scientific and engineering work is urgently needed to make it a more pleasant place to live in.

One of the most impressive features of recent months has been the way in which technical assistance and economic help to the developing countries, quite apart from the campaign against hunger, have been seen as a positive measure towards world peace and order. Nor is recognition of their social responsibilities confined to Western scientists: the Science Council of Japan has prepared a statement on such responsibilities for issue when a proposed Fundamental Law on Scientific Research is enacted, and independently of this has expressed the opinion that the principles outlined in that Law and this statement should guide both scientists and governments.

Too much, however, must not be expected of scientists alone. What is required above all is some effective means by which they may discharge their responsibilities in co-operation and partnership with both government and community, and this involves some clear understanding of the function of politics as well as of science, and their respective limits. On this, Mrs. M. Gowing's recent book, *Britain and Atomic Energy, 1939–1945* †, is full of suggestions. Even the scientist cannot always foresee the possible consequences of a particular development far ahead. Mrs. Gowing notes that Dr. C. G. Darwin, as he then was, had some appreciation of the implications of exploding a nuclear bomb when the Maud Committee reported in 1941, and wrote to Lord Hankey on the point. Another scientist closely concerned in the work reflected that perhaps the Committee should have studied the moral and political implications and considered its use more carefully.

† *Britain and Atomic Energy, 1939–1945*. By Margaret Gowing. With an introductory chapter by Kenneth Jay. Pp. xvi + 464 + 14 plates. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1964.) 55s. net.

The whole energies of the Committee, however, were directed to answering two questions: Was a uranium bomb scientifically possible ? and, if so, Could the British and their allies make one before the Germans ? At that early stage there was no dilemma for British scientists. The heartsearchings, described so vividly by Dr. A. H. Compton in *Atomic Quest*, came much later, and to expect more of the scientists at the early stage would be to confuse the issue, as well as to exercise hindsight. The scientist works not only within the framework set by his own scientific discipline but also within that set by the society within which he lives and the insight and traditions of that society.

In this context it is worth recalling some words of Sir Henry Tizard who, in his A. D. Little Memorial Lecture in 1951, referred to the deplorable intellectual gap between the students of science and the students of the so-called 'humanities' long before Sir Charles Snow (now Lord Snow) had given prominence to the term "the two cultures". That gap Sir Henry attributed to the failure of the humanists to move with the times. Even then, however, he thought humanists and scientists were coming much closer together. In that lecture he was concerned more particularly with the anxiety of scientists and technologists about the social implications of their work—anxiety which derived from the haunting fear that war on a large scale in future would altogether destroy civilization as we know it, and also from the fact that the application of scientific knowledge had so far brought only a fraction of the benefits to mankind which should have been possible.

Sir Henry does not countenance any dichotomy between scientist and politician. He reminds us pertinently that at one time it was quite normal for a man to gain a degree in science as a preparation for a career in law, in business or in public service, and he points out that scientists should study the political experience of other democracies with the object of adopting what is good and rejecting what is bad. The art of government rests on being in constant touch with the best advice available, and then making the experiment so that in the event of failure the *status quo ante* can be restored.

That may not always be possible, but Sir Henry was clearly right in stressing the importance of real teamwork in the social sciences. He holds also that if science is to have any real influence on national policy, some scientists must be prepared to spend part of their lives in the closest daily touch with men who formulate the policy. They must enjoy a reasonable measure of the confidence of their fellow scientists, who may be more gifted than themselves: but what is necessary is that they should study and appreciate all the ingredients of political decisions, including the ingredient of human nature—the most refractory material known to science.

There can thus be only welcome for the appointment by the British Government of a Minister of State in the Foreign Office to deal expressly with disarmament. The Prime Minister on November 19 said that the appointment gave practical expression to the importance attached to a fresh initiative by Britain. Mr. A. Gwynne-Jones would be advised on scientific aspects of his work by Sir Solly Zuckerman, who has been advising successive Governments on the scientific aspects of war and defence since 1939 and is still chief scientific adviser to the Ministry of Defence. How far the Government proposes to go remains to be seen. In his Guildhall speech on November 16, the Prime Minister was resolute as to the Government's

keep Britain's defence strong, and also to the Atlantic Alliance and to endeavour to e effective means by which the United Nations in to keep the peace and prevent small clashes lating into big ones. Equally it was its intention initiatives in disarmament whenever the opportrose or could be created.

clear intention to keep disarmament in the foreimplies some consideration of the consequences of rmament as well as of the means by which it can be ieved. The increased attention which is now being rected generally to those economic and social consequences may indicate that, despite all the technical and political difficulties, practical steps towards disarmament are not so remote as would at first appear. Taken with the Prime Minister's firm assertions on defence, the organization which the Government is establishing should help to ensure that when the time is ripe Britain is prepared with the economic and social measures which must be the counterpart of any reduction in armaments. One preparatory step must be the education of public opinion for the necessary changes, and in this connexion it is significant as well as welcome that the November 1964 issue of *The Unesco Courier*, which contains the text of the Nuclear Test Ban Treaty of August 1963, includes also several articles on these social and economic aspects of disarmament.

THE FOUNDER OF MODERN ATOMIC PHYSICS

J. J. Thomson and the Cavendish Laboratory in his Day

By Sir George Paget Thomson. (British Men of Science.) Pp. xi + 186 + 20 plates. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1964.) 25*s*. net.

THIS short biography of Sir J. J. Thomson by his son is one of a series on *British Men of Science* intended for the general reader.

'J.J.' entered Owens College, soon to become the Victoria University of Manchester, at the early age of fourteen and studied engineering, mathematics, physics and chemistry—Owens being one of the few Colleges with a physics laboratory at that time. At the age of nineteen he tried for a scholarship at Trinity College, Cambridge, but did not even qualify for an Exhibition. He tried again the following year and obtained a minor scholarship and sizarship and entered Trinity College to take the Mathematical Tripos at the age of twenty. At this time Clerk Maxwell was Cavendish professor. J.J. became second Wrangler and second Smith's prizeman, with Joseph Larmor in the lead. At the early age of twenty-eight, he succeeded Rayleigh as Cavendish professor and began work on the discharge of electricity through rarefied gases. This was a time when Hertz, Lenard, Perrin, Schuster and Wiechert were experimenting with the cathode rays. The discovery of X-rays by Roentgen in 1895 led J.J. to work on the ionizing properties of the X-rays. He then moved on to his successful measurement of e/m for the electron. Hertz had tried this experiment but failed, and J.J. was successful entirely because of the improved vacuum he was able to produce by using the better vacuum pumps then available due to the development of the electric lamp industry—an interesting example of feed-back from technology. Working in the Cavendish in those days were Townsend, C. T. R. Wilson and Rutherford, newly arrived from New Zealand and soon to go on to McGill University. The Laboratory staff included such characters as W. G. Pye, later to found Pye Instrument Company, Everett—J.J.'s assistant—Hayles, who in later years became Rutherford's book-keeper/secretary in the Cavendish of the 1920's, and Lincoln, famous for his moustaches, the laboratory steward of the 1920's. F. W. Aston, who worked with J. J. Thomson in later years, said: "Working under him never lacked thrills. When results were coming out well, his boundless, indeed childlike, enthusiasm was contagious and occasionally embarrassing. Negatives just developed had actually to be hidden away for fear he would handle them while they were still wet, yet when hitches occurred and the exasperating vagaries of an apparatus had reduced a man who designed, built and worked with it to baffled despair, along would shuffle this remarkable being, who, after cogitating in the characteristic attitude over his funny old desk in the corner and jotting down a few figures and formula in his tiny handwriting on the back of somebody's Fellowship thesis or an old envelope or even the laboratory cheque book, would produce a luminous suggestion like a rabbit out of a hat, not only revealing the cause of the trouble but also the means of a cure."

Another chapter describes J.J.'s work on positive rays and isotopes, which was started in 1905, following Wien's work on the measurement of e/m for the 'canal rays' discovered by Goldstein in 1866. J.J.'s improved vacuum technique led to his well-known parabolas and to the separation of the neon isotopes and thence to the mass spectrograph.

The author refers to the discussions at Farnborough—now the Royal Aircraft Establishment, Farnborough—in mid-1915 between Aston and Lindemann on whether the 22 parabola was due to $NeH_2.CO_2$. Lindemann always won the argument but "Aston had faith and was unbeatable". He returned to the Cavendish after the First World War to prove this by his mass spectrograph.

J.J. founded the Cavendish Physical Society for weekly discussions of laboratory experimental work, interspersed with lectures by visiting scientists; also the Cavendish tea-hour which was and is an occasion for general conversation rather than scientific discussion.

J.J. was interested in cricket, especially Lancashire cricket, and was also a keen supporter of the University Rugby Club. His greatest hobby was flowers, both wild and cultivated, and he made yearly pilgrimages to places near Cambridge when favourite flowers were in bloom.

In 1918 J.J. became Master of Trinity and handed over the Cavendish professorship to Rutherford, but continued to work in the part of the laboratory known as "the Garage". Here his assistant Everett presided over and erected variations of the maze of glass tubing where his experiments were carried out and J.J. appeared punctually at 1.00 p.m. every day to hear about the results of the experiments. He continued to lecture in the Cavendish, but his views of physics were by now rather conservative.

During the First World War he was chairman of a Royal Commission set up to report on the position of Natural Science in the educational system of Britain. Many of his views are still relevant to-day. He felt that the famous schools were too apt to tempt boys into classics at an early age by their system of scholarships. He valued an education which retained the boys' interest and freshness. Evidence was presented to the Royal Commission that boys who were to compete for entrance scholarships did little in the two years before the examination other than write out answers to papers set in previous examinations. Under this system the boys became more and more fed up with mathematics the more they persevered with it. He believed that some teaching was a positive advantage to a man's research and that interruptions at the right time helped original thought.

Sir George Thomson's biography gives a good account of a very great scientist.

J. COCKCROFT

BIOGEOGRAPHY OF THE PACIFIC BASIN

Pacific Basin Biogeography

A Symposium. General Editor: J. Linsley Gressitt. (Tenth Pacific Science Congress, Honolulu, Hawaii, 1961.) Pp. ix+563. (Honolulu, Hawaii: Bishop Museum Press, 1963.) n.p.

RECENT geophysical and geological investigations of the Pacific basin have done much to elucidate the past configuration of land and sea, and so define for biogeographers the conditions under which observed distribution patterns of animals and plants arose. This new information, even though swamped at times by more traditional inferences from biotic distribution, lends especial interest to this latest discussion of the biogeography of the region, the proceedings of a symposium on "Pacific Basin Biogeography" organized during the tenth Pacific Science Congress.

Because the Pacific basin is flanked by five out of the six great biogeographical regions and spans all climatic zones, the symposium was wisely subdivided. The first section considered relationships between nearctic and palæarctic plants, insects, birds and mammals across Bering Strait, and revealed a remarkable agreement in evidence and deduction. At various periods in the Tertiary and Quaternary Periods, continuous land linking Asia and North America permitted floral and faunal exchange, especially and most recently of tundra and taiga species. An unglaciated refugium in this area during glacial maximum appears to have been a centre for subsequent dispersal. In contrast, the Aleutian arc seems to have been of minor significance as a 'stepping stone' dispersal route.

The second section of the symposium, concerned with the richer, more complex and perhaps older biotas of tropical regions, revealed less unanimity. Geological evidence points to the persistence of the Pacific basin at least since the mid-Cretaceous, and to many of the guyots in mid-ocean having formerly emerged as high islands available as distributional stepping stones. A pre-Cretaceous trans-Pacific tropical land bridge was, however, invoked by two eminent phytogeographers, although other botanists, ornithologists and entomologists united in regarding it as unnecessary and in ascribing a larger role to direct dispersal. In most respects the mid-Pacific archipelagoes are a part of the Oriental region and there is a progressive biotic attenuation as one passes eastwards from the putative source area of the Indo–Malay island chain. Eastward spread along present and past island groups may account for this pattern, and a longer time-scale than has sometimes been assumed and a greater density of islands in the past may explain also the more puzzling botanical anomalies. It is refreshing to find that the familiar and sterile controversies based on diverse subjective estimates of dispersal capacity in various taxonomic groups are at last being supplemented by direct evidence based on insect trapping from aircraft, and it is evident that such research, together with further taxonomic, palæogeographical and palæontological investigations are urgently needed.

In the Antarctic region problems characteristic of both tropical and northern Pacific are combined. Each major land mass projecting into the southern temperate zone has three biotic elements. One (including all land vertebrates) has northward affinities in each case, and appears to have dispersed mainly in the Tertiary when continents were arranged as they are to-day. The second element is one peculiar to each region. The third, numerically smallest, is the austral element, which shows a markedly disjunct distribution between the southern continents and poses major biogeographical problems. It may be subdivided into a neoaustral element reaching recent volcanic oceanic islands and showing evident dispersal capacity, and a larger palæoaustral element of continental [illegible] perhaps requires contiguous land for dispersal. [illegible] group includes ancient conifers such as the Pod[illegible] the cytotaxonomic examination of which is c[illegible] stimulating new lines of research brought ou[illegible] symposium. A valuable geological paper acc[illegible] biological evidence by suggesting that, whil[illegible] Cretaceous biogeographical distributions mu[illegible] considered on a basis of present continental po[illegible] pre-Cretaceous ones must take into account [illegible] approximation of southern land masses. The palæoau[illegible] biota may therefore provide a genuine example of a [illegible] and fauna dispersed overland before the disruption [illegible] great southern continent. But if this is so, it is necessar[illegible] to explain how land vertebrates (such as snakes, dinosaurs and early mammals) failed to accompany the forest trees from South America or Africa to Antarctica, New Zealand and Kerguelen.

As a whole, this symposium volume highlights the advances and defects of biogeography in recent years. There is still much subjective speculation on dispersal capacity, where direct experiment would be more valuable. There is still a tendency among biologists to regard the distribution of species as more permanent than that of continents. Insufficient attention is still being directed to geological and geophysical evidence, which can alone define for biologists the framework on which their material must be arranged. Relationships between taxa now spatially separated still need critical assessment using modern cytotaxonomic techniques. But it is encouraging, in a symposium of this kind, to find all these lines of thought given prominence in an appraisal of the distribution of so many groups of plant and animal over so vast an area.

M. W. HOLDGATE

AEROSOL BEHAVIOUR

The Mechanics of Aerosols

By N. A. Fuchs. Translated from the Russian by R. E. Daisley and Marina Fuchs. Translation edited by C. N. Davies. Revised and enlarged edition. Pp. xiii+408. (London and New York: Pergamon Press, 1964.) 120*s*. net.

THIS edition of *The Mechanics of Aerosols* is completely revised and enlarged, incorporating the author's original Russian publication of 1955 and an addendum of 1961. The main object of the book is to collect and examine critically both theoretical and experimental material relating to the mechanics of aerosols. This latter term is one chosen by N. A. Fuchs to embrace the movement of aerosol particles and clouds, the collision of particles and the hydrodynamic disintegration of aggregates.

The major topics covered embrace the classification of aerosols, including size and shape; steady rectilinear motion including non-sphericity, electric fields, radiometric forces, thermophoresis, photophoresis, and diffusiophoresis; non-uniform rectilinear motion including acoustic, hydrodynamic and electrostatic scattering; curvilinear motion including a detailed discussion of the theory of aerosol sampling; Brownian motion and diffusion including filtration and respiratory deposition; convective and turbulent diffusion including atmospheric dispersion and deposition; coagulation including thermal, polarization, ultrasonic and gravitational modes; and finally the dispersal of powder as aerosols. While existing experimental data are critically reviewed in relation to relevant basic theories, detailed information on measuring techniques is not included. Reference is made to no less than 886 reports published up to 1960.

The work is intended as a unifying theoretical source for a subject covered in a diversity of journals devoted to widely differing branches of science and technology. The

translators and the English editor are to be congratulated on producing a final work which scarcely ever reveals that English is not the original language of composition. The whole is a most scholarly and satisfying work, rigorous and yet imaginative in its analytical treatment of aerosol behaviour. Unlike some highly specialized technical works, this book is eminently readable. It is logical in presentation and full of incisive and perceptive comment on where future investigations might be directed.

The somewhat long delay in producing this English edition is presumably due to the complicated checking procedure adopted to ensure a rigorous translation. A good deal of work has naturally been published in this field since 1960, and in some topics, therefore, experimental data discussed are already incomplete. For example, the assessment of atmospheric dispersion using Pasquill's treatment, published in 1961, has been shown to be more accurate over long distances than Sutton's formulæ. Its use is preferred, for example, in most present-day reactor safety calculations. Furthermore, some previous work was reported in sources not available to the author. A future edition might include an analysis of the global atmospheric dispersion of aerosols together with a collation of those topics which have sufficient relevance to radioactive wastes.

There are, however, no major omissions in the subject dealt with, while the general treatment is so authoritative and rigorous as to guarantee this book as a standard reference work of lasting value. It will be of unquestionable worth to research workers in university, industrial and relevant applied research departments.

J. F. CROFT

MASS SPECTROMETRY IN NATURAL PRODUCT CHEMISTRY

Structure Elucidation of Natural Products by Mass Spectrometry

By Dr. Herbert Budzikiewicz, Dr. Carl Djerassi and Dr. Dudley Williams. Vol. 1: Alkaloids. (Holden-Day Series in Physical Techniques in Chemistry.) Pp. xi+233. (San Francisco and London: Holden-Day, Inc., 1964.) 10.50 dollars.

THE most striking development in post-War organic chemistry has been the intensive application of physical methods to the elucidation of molecular structure. The various spectroscopic techniques, ultra-violet, infra-red and nuclear magnetic resonance, can all give important information very quickly; X-ray crystal analysis still remains the ultimate and final arbiter of molecular architecture, but it is unfortunately very time-consuming. Now another physical weapon has been added to the armoury of the chemist, high resolution mass-spectrometry, and, although this technique has been in general use only since 1960, the results achieved have been spectacular.

In Volume 1 of *Structure Elucidation of Natural Products by Mass Spectrometry*, the three authors—all pioneers in this field—confine their attention to alkaloids. This group of natural products presents a very favourable situation for the interpretation of cracking-patterns, since the first effect of electron impact is to remove an electron from the basic nitrogen atom leaving an ion-radical, the following homolytic fragmentation of which can usually be fairly easily predicted. Examples of various types of fragmentation are given, with particular reference to the various groups of indole alkaloids. Indeed, it is in this particular field that mass spectrometry has scored some of its most striking successes—complete structure determination of very complex molecules using only a few milligrams of material and with an absolute minimal recourse to 'chemical' operations. Among other alkaloids discussed are the isoquinoline, emetine, colchicine, lycopodium and quinazolone groups.

This is an admirable book which every practising organic chemist concerned with natural products will need to read: the immense power of the techniques described is fast changing the whole face of the subject. A further work, covering steroids and terpenoids, is promised shortly. At the end of their preface, the authors thank their publisher "for sharing our feeling that, if newspapers can be produced from one day to the next, books—which are generally shorter than the Sunday Edition of the New York Times—need not take more than ninety days". Other publishers of similar urgently awaited material, please note.

J. HARLEY-MASON

EXPANDING HORIZONS IN PHARMACY

Advances in Pharmaceutical Sciences

Vol. 1. Edited by H. S. Bean, A. H. Beckett and J. E. Carless. Pp. xi+334. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1964.) 75*s*.

"THE aim of this new series is to concentrate on areas of specific interest to the pharmaceutist . . .". For the uninitiated, pharmaceutist and pharmacist are synonymous in the Pharmacy Acts. Further, "The articles will be an appraisal of a subject rather than a mere factual abstraction of the literature".

The aims are praiseworthy, and although the four subjects chosen for this volume are of wide interest, the authors have included pharmaceutical applications.

The chapter on rheology is well written and is aimed at the undergraduate level. The theoretical section is brief, and the simpler concepts are dealt with in an explicit manner. The section on instruments is mainly descriptive and may be improved by a greater appraisal of the limitations and use of the instruments described.

The review is most concerned with solid/liquid and liquid/liquid systems, so that the perfunctory treatment of powders and the omission of the compression of powders is understandable. The systems and processes in which rheological properties are important are listed and should be useful in directing the attention of a pharmacist to the need for extensive work. This last section is good, but the factors affecting the viscosity of suspensions should also be included under emulsions, with the exception of the 'shape factor'. The use of Stokes's equation, which does not include a volume fraction term, for describing the rate of creaming of an emulsion is best avoided as the impression remains that the viscosity of the continuous phase, rather than that of the system, is important.

The first three sections of "Solubility in Systems Containing Surface Active Agents" gives a good review of the relevant ideas on micelle formation and solubilization. The last two sections, too, are very well done and contain an admirable summary of published information which is probably of greater value to the postgraduate worker.

Unfortunately, in the section on phase equilibria, the systems are not adequately described, most of the phase diagrams included are not even mentioned in the text, and the symbols used are not consistent in all the diagrams. If this section could be improved to the level of the rest of the chapter it would be a valuable summary for pharmacy students.

Mrs. Wedderburn has produced a very carefully written appraisal of a difficult subject in the chapter on "Preservation of Emulsions against Microbial Attack". It was enjoyable to read and easy to understand, since the problems involved were well discussed. Apart from those for internal use, the difference between cosmetic and pharmaceutical emulsions is one of degree, since cosmetics

are meant to be used on healthy skin, and this could have been emphasized a little more, particularly with reference to irritancy. On p. 260 the use of "soil or other solid matter" as a test inoculum is not recommended, but in view of her experience of a laboratory contaminant, lower down the page, I feel that soil, shelf dust, hay dust, etc., may be a wise adjunct to the more systematic testing.

The article "Contemporary Trends in Heat Sterilisation" is not so good as the rest of the book. The first eight pages consist of snippets of information that are inadequately digested, and considerable reliance on a review by Rahn (1945) seems to imply that Rahn was responsible for the work cited. The reference to super-saturated steam (p. 277) is incorrect, so is the reference to metals having a high specific heat (p. 294), and a number of erroneous impressions are also conveyed which may be the result of poor phrasing, as with the dryness fraction which would not normally have a value greater than one if (1 − wetness fraction) is intended.

On p. 278, Fig. 3 gives no units for the abscissa and, if these are lb./in.^{2} in excess of atmospheric pressure, the temperatures and pressures are not correlated. Certainly this figure does not appear to refer to dryness fractions as implied in the text.

The occasional inclusion of some elementary practical detail, such as the description of calorimetry (p. 279), is unnecessary and out of keeping with the book as a whole. The main part of the chapter is a detailed description of the design of autoclaves and controls which are now available, and as such scarcely justifies the word 'trends' in the title. Section XXXIII, entitled "Heat Output", rather surprisingly refers to lagging, ventilation and servicing.

The editors must accept some responsibility for not maintaining the standard set by the preceding chapters, and it is to be hoped that in future volumes we shall see more 'appraisals' of the standard set by the authors of the three other sections.

E. Shotton

NERVOUS IMPULSE

The Conduction of the Nervous Impulse

By Prof. A. L. Hodgkin. (The Sherrington Lectures, VII.) Pp. 108. (Liverpool: The University Press, 1964.) n.p.

THE nervous impulse, how it is generated at a local site and how it is conducted along the nerve fibre, was the subject of the Sherrington Lectures given in 1961 by Prof. A. L. Hodgkin. These lectures, completed with an account of more recent work, have now been published in the form of a book. Hodgkin, working in the Physiology Laboratory at the University of Cambridge, is Foulerton Research Professor of the Royal Society and received the Nobel Prize in 1963.

Signals conducted along nerve fibres are transmitted as electrical events, as a rule as all-or-nothing signals with a sharp threshold, and an amplitude which is independent of the stimulus. The most essential structure for the nerve impulse is the cell membrane, which surrounds the axis cylinder of the nerve fibre. This membrane can be seen in the electron microscope, but not in the light microscope, and is about 10^{-6} cm thick. The membrane has permeability properties which are very intriguing because it is clear that these permeability properties are the basis for the nerve impulse. The electrolyte in the axis cylinder contains a high concentration of potassium and a low concentration of sodium, while the external solution contains much sodium and little potassium. The resting nerve membrane is only little permeable to ions, but the permeability to potassium is relatively large compared to that of other ions. The movement of potassium through the membrane results, therefore, in a current of such a direction that it tends to charge the membrane towards the electrochemical equilibrium potential for potassium, and, due to this current, a steady potential difference across the membrane is maintained during rest. The axis cylinder is some 60–90 mV negative relative to the external solution. The permeability to other ions, and the consequent ionic currents, of course also affects the membrane potential at rest, but to a smaller extent.

An analysis of the ionic currents associated with step changes of the membrane potential indicates that the membrane permeability depends on membrane potential and time. When the axis cylinder potential is changed in positive direction from its resting value, then the membrane undergoes an initial transient increase in sodium permeability. The sodium permeability increase is followed by an increase in potassium permeability. Both these permeability changes are continuous smooth functions of membrane potential and of time, but are independent of sodium and potassium concentrations. The result of complicated and tedious experimental and analytical work is a fairly complete formal description of these permeability changes. A number of empirical constants in a number of equations thus describe the specific ionic currents in the nerve membrane as associated with step changes in membrane potential. The same set of constants and basic equations might be expected to apply also for the condition that the membrane undergoes a more complicated change. Further, the equations might predict the action potential of the nerve. Numerical solutions indicate indeed that the equations very satisfactorily predict many of the known excitability properties of the nerve fibre.

The impulse mechanism in the nerve, and very likely also in muscle, is thus explained quantitatively on the basis of these specific permeability changes in the very thin surface membrane. The ionic currents are passive and are consequences of the permeability changes and the electro-chemical driving forces. Immediate energy requirement for impulse generation is thus available in the form of a concentration battery, that is, the unequal distribution of ions on both sides of the membrane.

The specific ionic membrane currents have also been measured with the aid of radioactive isotopes and the findings support the ionic theory for impulse conduction. While these measurements resolve the ionic fluxes in many ways more clearly than the electrical techniques, the isotope measurements lack a high time resolution. Isotope measurements are also directed towards another goal, to investigate the ionic fluxes against the electrochemical gradient. These fluxes require energy, and are ultimately necessary in order to maintain the concentration gradients across the membrane and thereby maintain the energy used during the impulse generation. Energy-rich phosphate compounds are evidently used by the nerve for the active ionic transports against the electrochemical gradients.

In the preface of *The Conduction of the Nervous Impulse*, Prof. Hodgkin writes: "... I talked mainly about experiments on which my colleagues and I had been engaged in the immediate past". When reading the book I found this true. The preface does not tell, however, that Hodgkin and his colleagues have radically changed our concepts of how the impulse is generated in the nerve. Neither is it mentioned that a very complete picture of the "Cambridge Nerve" is given.

The book is written in a straightforward style. Rather drastic simplifications of the basic material have been made, but made in a masterly fashion so that the distortions caused are negligible.

I like the book; without doubt it is the best summary of the nervous impulse I have read. I can warmly recommend it to students within the field, to students in neighbouring fields and to all those who want to obtain an understanding of how the nervous impulse is generated and conducted.

B. Frankenhaeuser

BIOLOGY OF THE ANTARCTIC SEAS

Biology of the Antarctic Seas

Edited by Milton O. Lee. (Antarctic Research Series, Vol. 1.) Pp. ix+186. (Washington, D.C.: American Geophysical Union of the National Academy of Sciences—National Research Council, 1964.) 10 dollars.

FIVE of the eight papers presented here are devoted to experimental biology, with contributions from J. S. Bunt, E. Z. El-Sayed, E. F. Mandelli and Y. Sugimura on primary organic production, D. E. Wohlschlag on the respiratory metabolism and ecology of some Antarctic fishes, and M. A. McWhinnie on temperature responses and tissue respiration in Antarctic crustacea, with special emphasis on the whale food, or krill, *Euphausia superba* Dana. Such investigations are fundamental to our understanding of the biology of the Antarctic seas, and it is hoped that many more of them will shortly follow from the laboratories that now girdle the continent. This does not, of course, imply that future research can now be left entirely to the experimenter ashore. For there is still much to do in the field, especially on the little-known floor of the wide circum-polar abyssal sea.

M. A. McWhinnie's examinations on live krill in U.S.N.S. *Eltanin* will interest all who have studied these animals from preserved specimens. He finds them, for example, most active and showing the lowest apparent mortality at temperatures of 0° C and below. The greatest activity, in fact, was seen at −1·5° C, the lowest temperature observed. This is perhaps to be expected, because a very large part of this vast circum-polar population, it has recently been shown[1], does exist for the greater part of the year at surface temperatures falling within this range.

At South Georgia, it is true, *E. superba* has been recorded commonly enough up to about 3·9° C, but this occurs only in summer, February—the warmest month. In warmer water it occurs only as a rare straggler. Once or twice it has been recorded just north of the Antarctic convergence, but its occurrence there is anomalous and can be attributed to vagaries in the Antarctic surface current in which it spends so much of its existence. In the *Eltanin* experiments, 4° C proved lethal within 24 h. Euphausians as a whole are notoriously difficult to keep alive, and Dr. McWhinnie is to be congratulated on maintaining some dozens of his specimens for nine days, and five for thirteen days.

I was particularly interested in Robert Menzies's account of the latest techniques for deep-sea trawling used in U.S.N.S. *Eltanin*. These methods, notably in so far as they permit a fairly accurate determination of duration of contact with the bottom, and a useful estimation of the length of warp required, will doubtless be used with advantage on deep south polar bottoms, if they are not in fact already in use. But there is no mention of the Antarctic in this paper, the work described having been done in the tropics between Panama and Valparaiso. This is a great pity, as Antarctica has its own special problems, not the least being the cumbering of the sea-bed with erratic stones and boulders dropped by ice breaking away from the continental land. The deep terrigenous ooze so often encountered in these high latitudes presents a further problem, requiring, as I have shown elsewhere[2], its own technique. Moreover, it has yet to be shown that Menzies's contention, that in the deep sea contact with foul bottom is responsible for only trifling loss of gear, will hold good round the south polar continent. Rocky ground, and especially erratic boulders, can in fact play havoc with trawls and dredges there, especially on the rather deep continental platform. I have seen a large trawl, shot in 1,000 fathoms, torn almost to ribbons, evidently through contact with stony ground. He comments, too, on the exceptionally poor yield of the 'smaller dominant members of the deep sea' by the massive 'Herring Otter Trawl' (HOT) used by the Danes in *Galathea*. Surely the answer to this is to have fine nets attached to the back of the trawl, which is the technique that was so successfully used in the Antarctic by the late Stanley Kemp and his associates more than thirty years ago.

In "Antarctic Foraminiferal Zonation", O. L. Bandy and R. J. Echols have given an interesting zoogeographical investigation. In high southern latitudes animals so small are prone to 'faunistic displacement', floating icebergs, formerly aground, often being responsible for carrying massive accumulations of bottom material to be deposited eventually in the most unexpected places. The recognition and sorting out of the distributional and bathymetric anomalies that spring from these phenomena are competently handled in this important paper.

Concluding this volume is an exhaustive catalogue and bibliography of the benthic marine algae compiled from a very scattered literature by George A. Papenfuss. It has 240 references going back to 1822.

BIRD SONG

A Study of Bird Song

By Edward A. Armstrong. Pp. xv+335+16 plates. (London: Oxford University Press, 1963.) 45*s*. net.

IT is well known that bird song is much more than a sweet expression of domestic emotion, that it conveys many things, including aggression, courtship, territory ownership and other bits of information important to birds in their social life. Hence, the investigation of the vocalization of birds is being actively pursued by workers in behaviour, communication and systematics, who frequently become recording enthusiasts. In *A Study of Bird Song*, Armstrong has brought together most of the information accumulated by these workers, and presented it neatly in a condensed and systematic fashion.

The body of the book is made up of chapters on song structure, its development, the variety of forms and functions of song, and determinants such as light, climate, and the associated breeding cycle. There is an introductory chapter on bird utterances as language, and a concluding one on song as art and play. An appendix surveys acoustic communication in the animal kingdom, and eleven pages of addenda take account of work appearing in two and a half years of delay in publication. There is a thorough bibliography and finally an excellent index with four divisions.

In the treatment of such a broad-ranging subject, no unifying theme is found, and probably none is possible. The first chapter, on bird utterances, directs attention to the wide range of avian vocal signals and their rich content of information. A useful review is included of the sound signal repertoires found in the dozen or so species which have been examined in this respect.

Several chapters on the structure and components of song and on its development summarize much of the information available on this subject at the time of writing. Regarding structure, the emphasis placed on measures of pitch, loudness and quality of bird sounds gives undue importance to these aspects, neglecting the complex internal structure of the song as a whole, which is revealed in more recent audiospectrographic investigations. In this section there is an illuminating review and discussion of terminology in bird song. A typical suggestion for better usage is the substitution of 'song version' for 'song type' or 'song pattern'. Armstrong rejects,

however, the progress which has been made in the use of the important term 'subsong' by referring it to all forms of quiet song. Thorpe's restrictive definition based on acoustic characteristics which is discarded is, in fact, a model of clarity which ought to be imitated in the definition of other vague terms, such as that of song itself.

The strength of this book, its wide-ranging comprehensiveness, is also the source of a weakness, which is a tendency to overlook differences in the quality of evidence. The importance of results obtained with modern instruments and critical experiments is not sufficiently emphasized. It is disappointing to find the experimental results obtained by Thorpe on song in the chaffinch placed on the same footing as the observations of bird fanciers. The latter have known long ago that experience plays a part in the development of song, but such information is usually anecdotal in character and mixed with unreliable notions which must be tested.

In the later chapters there are many interesting pages on such topics as mimicry, dialects, duetting, and the variety of functions performed by song. There are numerous useful suggestions and critical comments on the interpretation of the facts, and indications of directions for fruitful future research. Anyone who has seriously asked if singing birds possess an æsthetic sense will enjoy the final chapter on bird song as art and play. Perhaps the disagreement reflected in the discussion of C. Hartshorne's ideas on the effect of the monotony threshold will stimulate research on this interesting hypothesis. The book will join earlier works by this author as an important contribution to the investigation of bird song, serving as a comprehensive guide to the work carried out and a valuable aid to the formation of general principles in this subject.

J. A. Mulligan

NATURAL PLANT GROWTH REGULATORS

Régulateurs Naturels de la Croissance Végétale

(Colloques Internationaux du Centre National de la Recherche Scientifique, No. 123, Gif-sur-Yvette, 15–20 Juillet, 1963.) Pp. 748. (Paris: Edition du Centre National de la Recherche Scientifique, 1964.) n.p.

Régulateurs Naturels de la Croissance Végétale reports the proceedings of the fifth in the series of international conferences on plant growth regulators, which was held at Gif-sur-Yvette in July 1963, under the auspices of the Centre National de la Recherche Scientifique. Most of the text is, however, in English. These colloquia provide an opportunity of surveying the rapidly developing subject of plant growth substances. This subject is now very wide, covering a large range of synthetic substances including weedkillers, so the restriction in this colloquium to natural growth regulators not only kept the subject within bounds, but also re-emphasized the importance of understanding the occurrence and action of naturally occurring substances which is essential to an understanding of the action of synthetic substances.

The organizers are to be congratulated on their choice of topics, so that the roles of plant growth substances from cell division to senescence were discussed in a comprehensive manner.

Twelve papers are concerned with the regulation of cell division. The introductory papers describe the complex molecular mechanisms of cellular regulation which are necessary for cell division and the processes which anticipate mitosis. Interest in cell division factors in plants is at present centred on the environment of the embryo, and several papers describe the isolation and characterization of substances from developing seeds and fruits. Coconut milk contains cell division factors, and it is not surprising, therefore, that much of the effect in this field has been directed to the isolation and characterization of substances which induce cell division in plant tissue cultures. The results are, at the moment, somewhat contradictory, and several substances, belonging to widely different chemical groups, have been identified which accelerate cell division; however, the isolation of three different phytokinins in coconut milk is probably significant. Progress is hampered by lack of a comprehensive range of bioassay methods for cell division factors. The interesting fact is recorded that the bleeding sap of *Vitis* also contains phytokinin-like substances which are probably synthesized in the root. Phytokinins may have effects other than on cell division, and their regulating effects on attraction and retention of nutrients have important implications in the transport of such substances to 'sinks', especially immature seeds and fruits. The largest section (sixteen papers) is concerned with the regulation of cell enlargement. Much of the effort is at present concerned with the form in which indoles occur in the plant and their transformation during growth. There is evidence that auxin interacts with macromolecular constituents of plants, for example, RNA. Six of this group of papers discuss the role of gibberellins, including their biosynthesis.

We know less of the occurrence and nature of natural growth inhibitors than of growth-promoting substances. One difficulty is to know whether a substance which acts as a growth inhibitor *in vitro* has the same role *in vivo*. This problem is well illustrated in five papers concerned with synergists and natural inhibitors. Some naturally occurring phenolic substances inhibit the growth of plant tissues at high concentration, but at lower concentrations growth may be stimulated. This suggested that such substances exert their effect through the indoleacetic acid oxidase system. In a discussion on dormancy it is pointed out that 'rest' stages of plant organs may be due either to the presence of growth-inhibiting substances or absence of growth-promoting substances. The first hypothesis is supported by a correlation between seasonal changes in bud dormancy and corresponding variations in the level of endogenous inhibitors.

Success in isolating the true growth-promoting substances from plants depends on the methods used. This problem is discussed in five papers using techniques of gas, paper and thin-layer chromatography and spectrophotofluorimetry.

Our knowledge of how growth substances regulate vegetative growth is still meagre. Widely ranging aspects of this topic are presented in seven papers and include the relative contributions of cell division and cell expansion to growth, the relation between contents of auxin and gibberellins to leaf growth, the substances governing root initiation and root growth. The polar transport of auxin and its modifications by unilateral influences have important implications in explaining geotropism and phototropism. The demonstration of the presence of minute crystalline bodies in apical cells of the *Avena* coleoptile which may act as photoreceptors in phototropism is a significant advance. The chapters on the regulation of flowering are mainly concerned with identification of substances which cause bolting or induce flower differentiation. No one can yet claim to have characterized such a substance, but it is encouraging that active crystalline extracts have been prepared. Finally, the four papers on senescence indicate the progress made towards an understanding of abscission processes and the role of phytokinins in regulation of leaf senescence.

This volume summarizes our knowledge of plant growth substances up to 1963 but, with rapid developments in this field, the information will soon be out of date. It is perhaps unfortunate, therefore, that it was considered necessary to have such a luxurious production.

E. C. Humphries

British Defence Policy and Nuclear War

By Emmaniel J. de Kadt. Pp. 148. (London: Frank Cass and Co., Ltd., 1964.) 21*s*. net.

THE question whether Britain should or should not continue to centre her defence policy on an independent nuclear force is now under re-examination by a new Government, and the responsibility may well force a more searching examination of the question than it has received from some of its opponents when out of office. Mr. de Kadt's book should assist in the independent and critical appraisal of a problem, inherently difficult and not to be further obscured by prejudice or preconceived ideas. His chapters outlining the nuclear strategies of the Western world and the development of the British nuclear deterrent are perhaps a little sketchy, but they display the inconsistencies and defects of successive White Papers on defence. The real value of *British Defence Policy and Nuclear War* lies in the five chapters which examine pragmatically the limitations or failure of deterrence, the function and limitations of civil defence and the situation which is likely to be encountered in Britain as a result of the use of nuclear weapons under conditions which are the most conceivable if, in fact, such weapons are used. The issues raised are inescapable, if often neglected or ignored, and Mr. de Kadt's treatment is sound, though perhaps open to criticism on detail. He does, perhaps, rather less than justice to the missile-firing submarine—on this Capt. S. W. Roskill's final chapter in *The Strategy of Sea Power* offers a firmer guide—but Capt. Roskill is just as emphatic as Mr. de Kadt that it is imperative for Britain to do everything possible to minimize the chances of nuclear attack ever happening. Even more interesting is its insistence that with the examination of the potential consequences of war must come the investigation of apparent barriers to peace. It is not for economic reasons alone that the appointment of a Minister of State to deal with disarmament is a logical part of foreign policy as well as of defence. It is a practical recognition of the fork in the road emphasized by Mr. G. Piel, and a definite step towards the policy of national security which Mr. de Kadt seeks to promote.

The Fabulous Isotopes

By Robin McKown. Pp. 189. (London: Macmillan and Co., Ltd., 1964.) 21*s*. net.

THIS book, intended for the general reader or as background reading for the senior school pupil, is an American attempt to popularize, in the best sense of the word, a field in atomic physics. It is simply and engagingly written and is generally accurate. The sections on the uses of isotopes seem to be better than the theoretical introduction concerning their nature. The illustrations are clear and helpful. The English reader will have to master American spellings which his English teacher might not accept. It is doubtful whether "about the size of a cantaloupe" will assist him in visualizing the dimensions of a miniature atomic power plant, to the working of which, incidentally, no clue is given.

Like so many other popular works, this book reveals the tremendous difficulties which beset an author of this kind of literature. To achieve the accuracy of statement which is the *sine qua non* of scientific writing is difficult enough. The present work, though largely concerned with neutrons, fails to mention the name of Chadwick. A simple explanation of the cloud chamber is given, but, although the Geiger counter is constantly mentioned, no explanation of its mode of action, or who Geiger was, is forthcoming. The old myth of Henri Becquerel accidentally leaving a piece of uranium ore on top of a photographic film is perpetuated and, incidentally, the date of his experiment is given wrongly. Here a real chance of a simple explanation of a planned experiment is lost.

The truth of the matter is that within a few weeks of the publication of Röntgen's X-ray paper, Becquerel, having read it, intelligently experimented to try to find a complementary or reciprocal phenomenon. The result of his experiments did not verify his hypothesis but quickly led him to the discovery of radioactivity.

The date of the discovery of artificial radioactivity is given as 1934 in the text and two years earlier in the summary. The positron appears in the text with the Curie-Joliots and in the summary with C. D. Anderson. These small points could be cleared up in a second edition.

Finally, the book raises some pedagogical questions in my mind, of which the following are specimens: Is there any virtue in printing a decimal fraction with twenty-seven noughts, to give an idea of the mass of an electron? The equation $e = mc^2$ is given, and the velocity of light appears as 186,000 miles per second. What units will the enquiring secondary-school pupil give to e? If text-books and popular books on science are to achieve optimum results their authors will have to consider painstakingly the nature of concept formation in relation to the intelligence and maturation levels of their readers.

W. L. SUMNER

Tumours of the Kidney and Ureter

Edited by Sir Eric Riches. (Neoplastic Disease at Various Sites, Vol. 5.) Pp. xv+416. (Edinburgh and London: E. and S. Livingstone, Ltd., 1964.) 90*s*. net.

COMPARED with other forms of neoplastic disease, tumours of the kidney evoke particular interest not only on account of their varied nature and behaviour, but because of recent developments in their earlier diagnosis and treatment. In bringing out this important monograph, Sir Eric Riches is to be congratulated on enlisting the support of a number of colleagues who have been carefully chosen to supplement his own unique experience. Thus, in addition to the statistical data which provide a regular feature of the series, authoritative sections are contributed by Dr. Cuthbert Dukes on the causation of renal neoplasms, by Dr. A. C. Thackray on their pathology and by Mr. D. Innes-Williams on tumours of the kidney in infancy and childhood. Among other contributions those by Sir Brian Windeyer on radiotherapy and by Dr. H. J. G. Bloom on hormone treatment are of particular practical importance.

The main message of the book, however, is conveyed by the description and analysis of renal tumours in adult life—by Sir Eric Riches, whose experience in this field is probably unparalleled and in which his numerous contributions have achieved international renown. This is supported by a wealth of illustrations in which the macroscopic features of the tumour are superimposed on the X-ray films so as to emphasize the importance of radiological interpretation. This theme is elaborated further by Dr. C. G. Whiteside and Dr. John L. Emmett, who refer respectively to the role of pyelography and arteriography, and nephrotomography in X-ray diagnosis. Other subjects of present-day interest which are discussed include the value of cytological diagnosis, the significance of polycythæmia and the association of renal tumours with hypertension. Perhaps the most important practical feature, however, is the section devoted to prognosis in which the results of an earlier series presented to the British Association of Urological Surgeons are expanded. Here the outlook is correlated with the pathological grading and extension of the disease at the time of surgical treatment in such a manner as to provide a valuable indication of what to expect.

In summary, the book, which is excellently produced, provides a comprehensive yet discriminative account of existing knowledge regarding the detection and management of renal neoplasm which will surely prove of value to all engaged in the investigation of this form of disease.

J. D. FERGUSSON

35-Gc/s, 70-Gc/s AND 94-Gc/s CYTHEREAN RADIATION

By Prof. C. W. TOLBERT and Prof. A. W. STRAITON
Electrical Engineering Research Laboratory, Austin, Texas

INTEREST in Cytherean radiating characteristics, defined by measurements at many different wavelengths on many different occasions, has been heightened by the prospect of physical exploration of Venus by the National Aeronautics and Space Administration, and many and varied models have been proposed to explain the level of radiation[1–5]. To resolve some of the degrees of modelling freedom allowed by the observed spectrum an extension of measured values of brightness temperatures into the domain of the millimetre wave-lengths is required. The millimetre wave-length observations must be conducted with the resolution of both line and continuum spectra in order to obtain information on the physical nature of the source that is available through the radiation and absorption of gaseous line spectra.

The measurements to be described in this article were conducted at frequencies of 35 Gc/s, 70 Gc/s and 94 Gc/s with a 16-ft. diameter antenna[6]. The 35-Gc/s measurements were made to associate the relative brightness temperature of the three frequencies to the brightness temperature of a frequency at which a number of measurements have been reported. While the three frequencies are too widely spaced to yield significant line spectra and even the bandwidth of the radiometer at each frequency is excessively wide for low-pressure gas line resolution, the absorption minima of the Earth's atmosphere at 35 Gc/s and 94 Gc/s make these frequencies attractive for Earth-based observations. By including 70 Gc/s, a frequency at which components are conveniently available and a frequency as far removed from the other two as the oxygen absorption in the Earth's atmosphere will allow normal Earth-based observations to be, a crudely defined spectrum was hoped for.

Conventionally designed Dicke-type a.c. radiometers with 30-c/s mechanical modulators were used in conjunction with the 16-ft. mm wave-length antenna system for the measurements. The root mean square uncertainties of the radiometers were 1° C, 5° C and 7° C for integrating periods of 1 sec at the frequencies of 35 Gc/s, 70 Gc/s and 94 Gc/s, respectively. The radio frequency components and the 10-Mc/s bandwidth intermediate frequency pre-amplifiers were incorporated at each frequency with the antenna feed horns and supported singularly by the antenna spars at the prime focusing of the 16-ft. parabola. The feed horns accepted 10 dB periphery tapered energy from the parabola with resulting antenna gains of 62·5 dB, 68·5 dB and 70·9 dB, at the frequencies of 35 Gc/s, 70 Gc/s and 94 Gc/s, respectively. The remainder of the radiometers, the intermediate frequency amplifier, the narrow bandwidth amplifier-synchronous detector and the assorted power supplies, were commonly used at three frequencies.

Analogue recordings of the millimetre telescope output were made during right ascension scans of the antenna beam across Venus. At each frequency the polar axis drive rate was adjusted to scan in the period of 10 radiometer time constants an angle relative to Venus equal to the antenna half-power beamwidths. Scans were repeated over an angle of ± 3 antenna beamwidths as frequently as possible when Venus was within ± 2 h of the meridian, and markers were applied to the data sample recordings when optical telescopes collimated with the millimetre telescope beam pointed at Venus.

The optical telescopes were collimated with the antenna beam by pointing the millimetre telescope for equal signals at the north–south point of the Moon and aligning

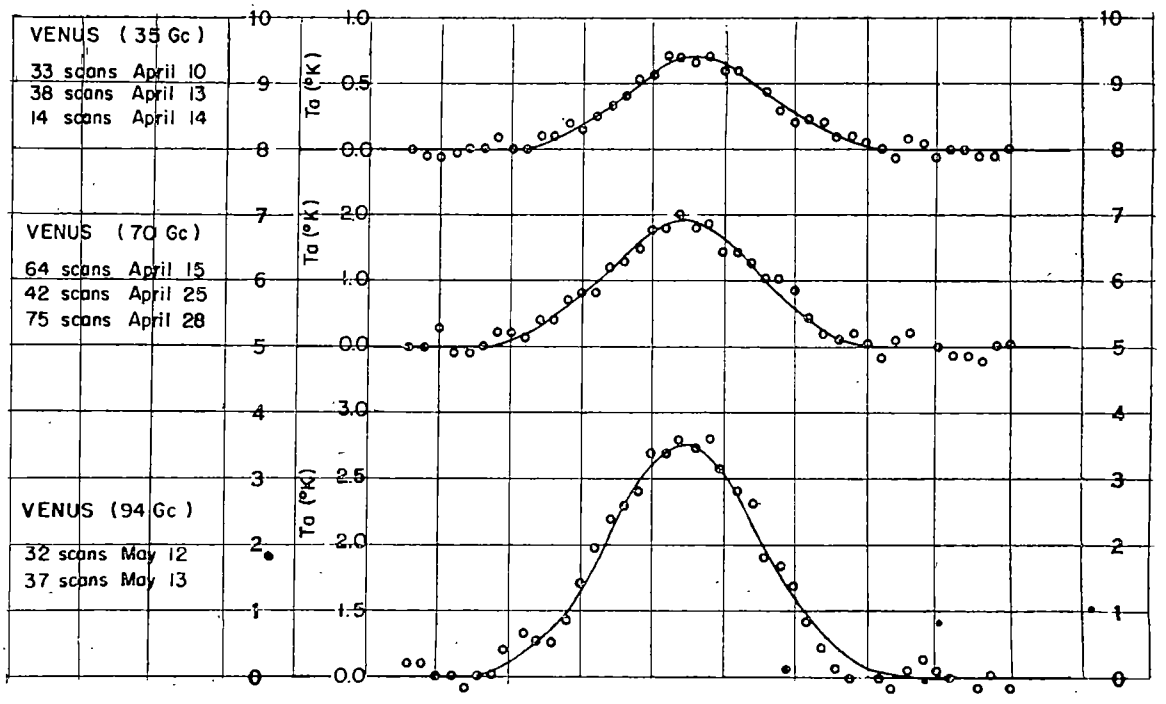

Fig. 1. Examples of antenna temperatures obtained from averages of data samples near eastern elongation

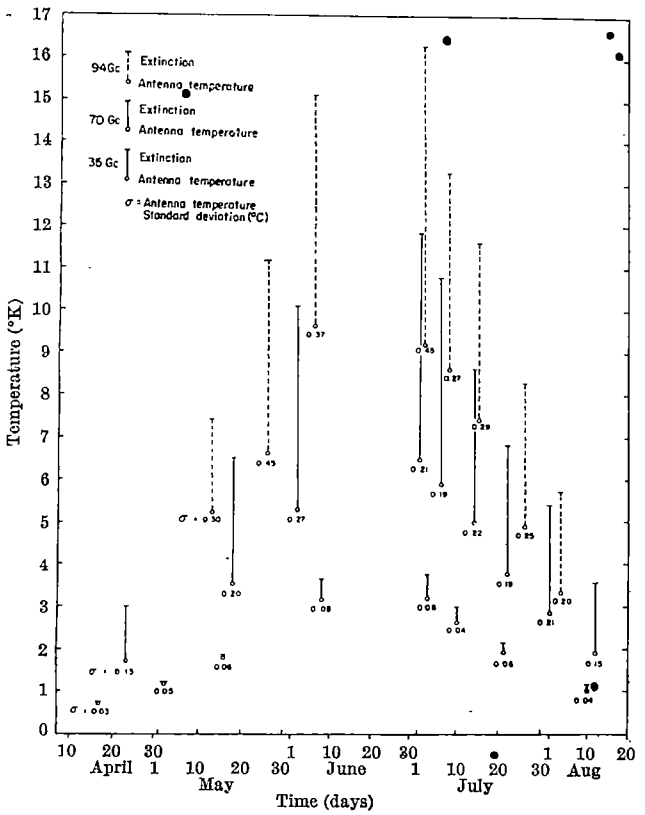

Fig. 2. The 35-, 70- and 94-Gc/s antenna temperatures and atmospheric extinction corrections

the cross-hair radicals of the telescopes with the limbs of the Moon. Collimation was performed at declination angles as near as possible to that of Venus to minimize optical-millimetre wave-length refraction differences and mechanical antenna beam-optical beam differences.

A single value of the atmospheric attenuation for an average value of altitude angle was used to evaluate the millimetre wave-length extinction each day. The attenuation values were derived from radiosonde data of the total precipitable water in the atmosphere. Wave-guide terminations immersed in boiling and tap water temperatures, electrically heated black bodies and gas noise tubes were used to calibrate the radiometer. The average full-scale pen and paper antenna temperature recordings were 6° C, 30° C and 40° C at the frequencies of 35 Gc/s, 70 Gc/s and 94 Gc/s, respectively.

Observations were attempted each day between April 10 and August 22, with the exception of those days omitted when Venus appeared within ± 1 h of the Sun setting. Data were excluded when clouds prevented optical confirmation of the antenna pointing, when during the approximately 3–6 min of a data sample scan, the variability of the emission and absorption of the atmosphere drastically disturbed the low-frequency components of the signal level or when the positions of the antenna side lobes relative to the Sun drastically disturbed the low-frequency components of the signal-level. Examples of the results obtained by averaging at 1/12 antenna beam-width intervals data samples from single days or groups of days are shown in Fig. 1. The solid curves are radiometer time constant transformed antenna pattern responses to point sources best-fitted to the measured values.

The brightness temperatures of Venus were evaluated from the antenna temperatures with the following expressions:

$$T_s = T_a \left[\frac{41{,}253}{(Ag)(K\Omega_s)(\Omega_s)^2}\right] e^{0.23\Gamma}$$

Where T_s is the source brightness temperature (°K), T_a, the antenna temperature (°K), Ag, the antenna gain (maximum relative to isotropic source), $K\Omega_s$, the antenna gain correction for source size, Ω_s, the angle subtending source (deg.) and Γ, the attenuation through the Earth's atmosphere (decibels), such that:

$\Gamma = 0{\cdot}10 + 0{\cdot}11\ (\rho_\omega)\ \sec\varphi$ (at 35 Gc/s)
$\Gamma = 1{\cdot}70 + 0{\cdot}16\ (\rho_\omega)\ \sec\varphi$ (at 70 Gc/s)
$\Gamma = 0{\cdot}65 + 0{\cdot}33\ (\rho_\omega)\ \sec\varphi$ (at 94 Gc/s)

ρ_ω is precipitable atmospheric water vapour (g/cm²), φ is zenith distance (degrees).

The uncertainties of the brightness temperatures are represented by the following expressions:

$$\Delta T_s = T_s \cdot A_p \pm \sqrt{(Ag^2) + (T_a)^2 + (T_c)^2 + (e^{0.23\Gamma})^2}$$

Where ΔT_s is the source temperature uncertainty, A_p, the antenna pointing uncertainty (5, 3 and 0 per cent at 94, 70 and 35 Gc/s, respectively), Ag, the antenna gain uncertainty (12, 8 and 5 per cent at 94, 70 and 35 Gc/s, respectively), T_a, the antenna temperature uncertainty (variable with number of data samples averaged), T_c, the temperature calibration uncertainty (5 per cent at 94, 70 and 35 Gc/s), and $e^{0.23\Gamma}$, the absorption uncertainty (5 per cent at 94, 70 and 35 Gc/s).

Graphs of the 35-, 70- and 94-Gc/s antenna temperatures as a function of time, graphically displaying the magnitude of the correction for atmospheric extinction, are shown in Fig. 2. The 35-, 70- and 94-Gc/s brightness temperatures of Venus as functions of time, Cytherean phase (included angle between the Earth, Venus and the Sun) and fractional Cytherean disk illuminated are shown in Fig. 3. The nominal brightness temperature uncertainties are +14 per cent −14 per cent at 35 Gc/s, +17 per cent −11 per cent at 70 Gc/s and +19 per cent −9 per cent at 94 Gc/s.

Temperatures of approximately 250° K and 350° K are prescribed for rapidly and synchronously rotating bodies, respectively, with an albedo of 0·7 at the position of Venus relative to the Sun. The spectral brightness temperature of Venus as defined by some of the measured values is

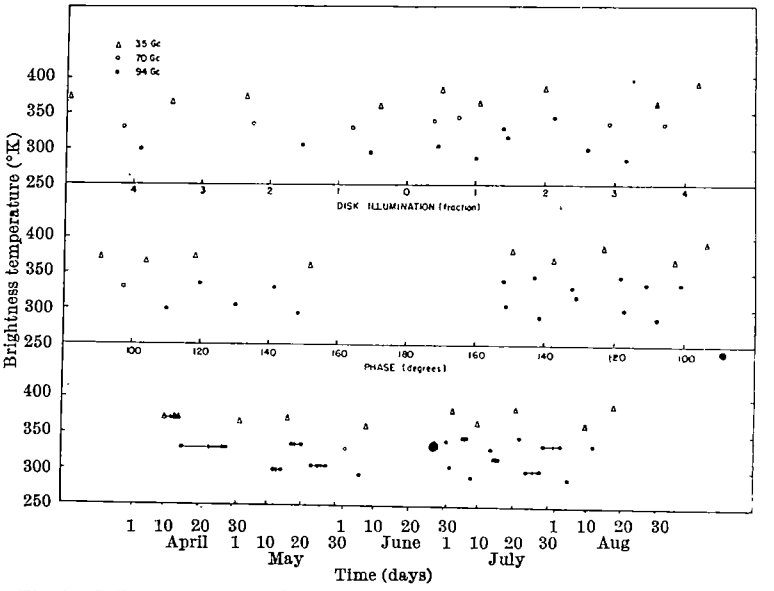

Fig. 3. Cytherean 35-, 70- and 94-Gc/s brightness temperatures as functions of time, phase and disk illumination

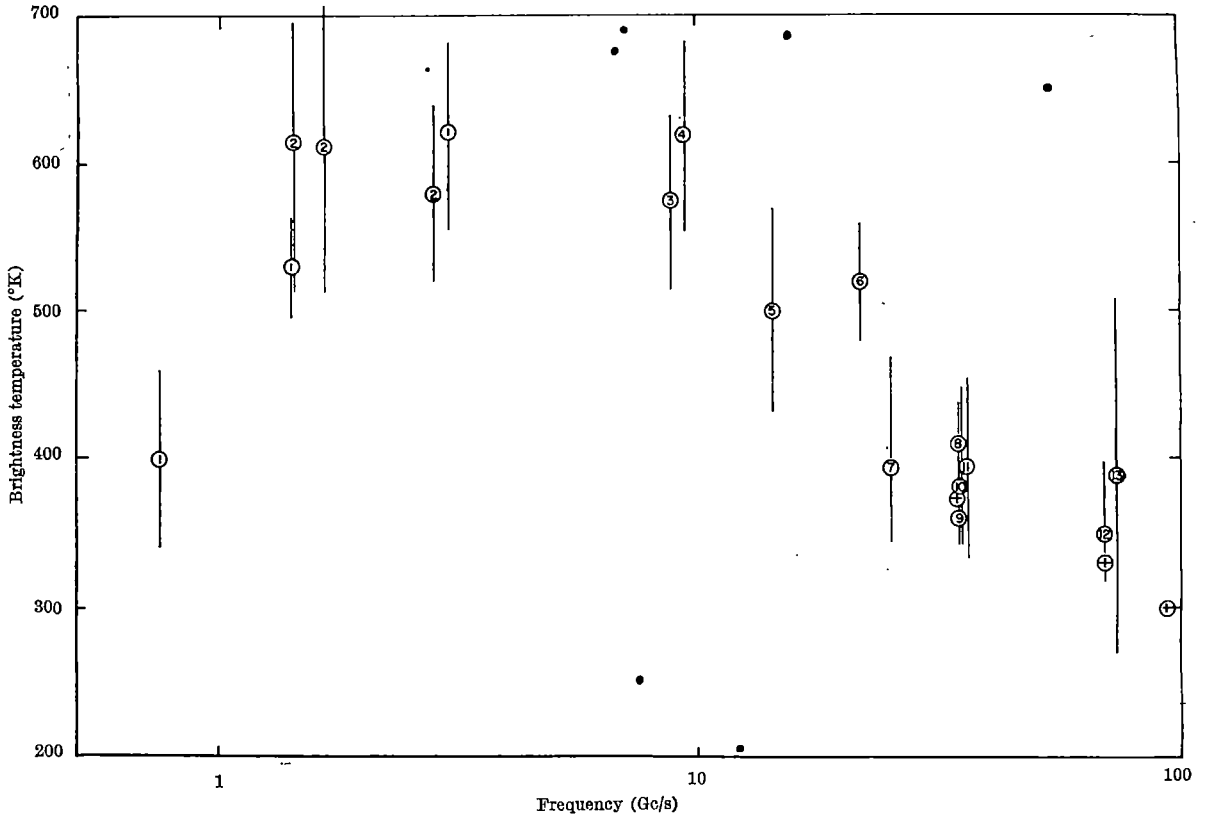

Fig. 4. Data representative of observations defining the spectral brightness temperature of Venus. 1, Drake, 1964; 2, Clark and Spencer, 1964; 3, Alsop, Giordmaine, Mayer and Townes, 1958; 4, Mayer, McCullough and Sloanaker, 1963; 5, McCullough and Boland, 1964; 6, Gibson and Corbett, 1963; 7, Staelin, Barrett and Kusse, 1964; 8, Gibson, 1963; 9, Copeland and Tyler, 1964; 10, Lynn, Meeks and Sohigian, 1964; 11, Thornton, 1964; 12, Grant, Corbett and Gibson, 1963; 13, Kislyakov, Kuz'min and Salomanovich, 1962; +, Tolbert and Straiton, this paper

shown in Fig. 4. The 35-, 70- and 94-Gc/s values are average temperatures measured between April 10 and August 22, 1964.

Planetary emission (T_e) can be represented by the expression

$$T_e = \sum_{i=1}^{n} \varepsilon T_i \, (1 - e^{-\alpha_i \Delta z_i \sec\theta}) \, e^{-\sum_{i=1}^{i-1} \alpha_{i-1} \Delta z_{i-1} \sec\theta}$$

T_e is emission temperature, T_i and α_i is temperature and attenuation of the element of depth Δz inward through the planetary mantle (atmosphere) and core (surface), ε is emissivity of planetary element, θ is angle of the observation relative to the emitting element zenith.

A summation of T_e for all values of θ over the planetary disk yields the brightness temperature. The zenith emission from an isothermal mantle and an isothermal core is:

$$T_e = T_m(1 - e^{-\tau}) + T_c e^{-\tau}$$

T_m is mantle temperature, T_c is core temperature, τ is $\int \alpha dz$.

The Cytherean spectrum can be described either by radiation from a hot core and a cold mantle increasingly opaque from 10 Gc/s to 100 Gc/s (thermal model)[1,3,4,7] or by radiation from a hot mantle decreasingly opaque from 10 Gc/s to 100 Gc/s and a cold core (non-thermal model)[2,5,8].

To obtain a hot-surface temperature, 'greenhouse' heating by a mantle of low optical wave-length opacity and high infra-red wave-length opacity (caused by a small density of a strongly absorbent gas, such as H_2O, or a large density of a weakly absorbent gas, such as carbon dioxide) or friction heating at the surface by wind-driven dust aerosols (agitated by solar radiation absorbed at high altitudes by dust clouds) have been proposed.

To obtain a hot-mantle temperature, free–free radiation from a high-density ionosphere (caused by solar ionization of the mantle in the absence of magnetic shielding) or radiation from charging and discharging of the large aerosol particles (resulting from the charge accumulation of precipitating particles) has been proposed.

Representative examples of the 10–100 Gc/s spectrum of each model are displayed with the measured brightness temperature values in Fig. 5. Within the uncertainty limits of the absolute brightness temperatures all models describe the observed spectrum.

Brightness temperatures at 3 Gc/s and 9·53 Gc/s as functions of Cytherean phase (i) are described by the following expressions[9,10]

(3 Gc/s) $\quad 622° \text{ K} + 41 \cos(i - 21)° \text{ K}$

(9·53 Gc/s) $\quad 621° \text{ K} + 73 \cos(i - 11{\cdot}7)° \text{ K}$

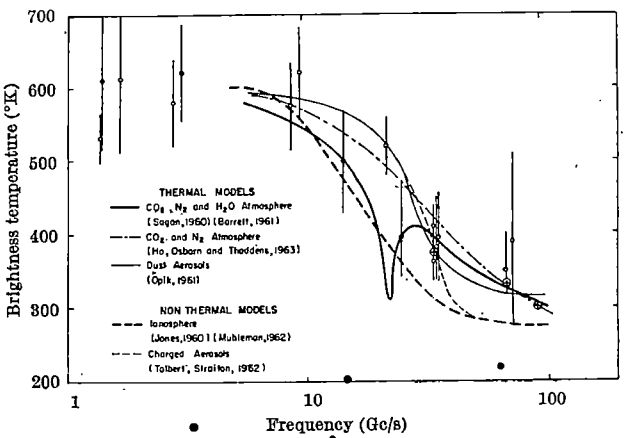

Fig. 5. Examples of spectra of proposed models describing the Cytherean radiating mechanism

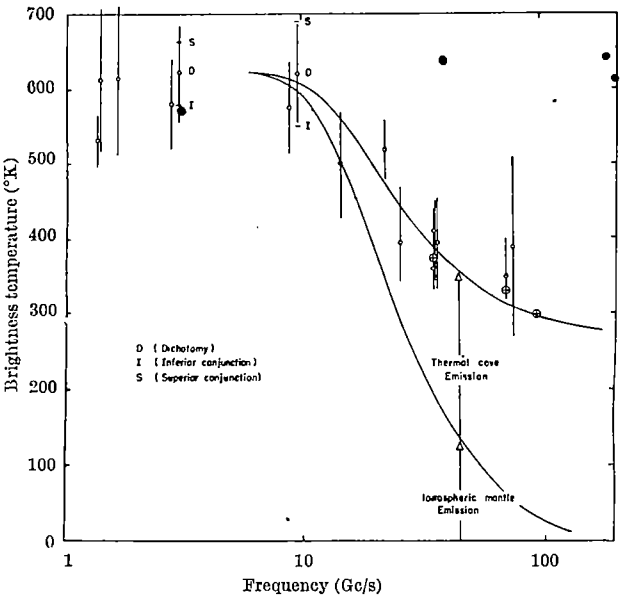

Fig. 6. Calculated ionospheric Cytherean spectrum best describing observations

Expressions of the Cytherean phase dependencies of the 35-, 70- and 94-Gc/s brightness temperature are unobtainable from the data due to the apparently small dependency factors relative to the uncertainties and sparseness of brightness values at each of the frequencies. The rank difference correlation coefficients of the Fraunhofer Institut sunspot indices, adjusted for the position of Venus relative to the Earth-based observations, with the millimetre brightness temperatures at 0·80 at 35 Gc/s, 0·75 at 70 Gc/s and 0·35 at 94 Gc/s. The quality of the correlation of the millimetre wave-length brightness temperature perturbations with the solar indices enhances the possibility that the Cytherean radiation is, in part, ionospheric.

Scaled millimetre wave-length phase-brightness temperatures from an average of the 3 Gc/s and 9·53 Gc/s phase-temperature characteristics based on an ionospheric model having a hot mantle and cold core of 620° K and 280° K, respectively (electron temperature $\sim 620°$ K, electron density $\sim 10^9$ cm^{-3} and integrated squared electron density through ionosphere is 10^{26} cm^{-5}), are as follows:

(35 Gc/s)	$375° \text{ K} + 17 \cos(i-x)° \text{ K}$
(70 Gc/s)	$330° \text{ K} + 9 \cos(i-x)° \text{ K}$
(94 Gc/s)	$300° \text{ K} + 4 \cos(i-x)° \text{ K}$

If any phase characteristic of the millimetre data of Fig. 3 is to be recognized there is an apparent phase advance of the millimetre wave-length minimum brightness temperature relative to that of the centimetre wave-lengths to a time preceding inferior conjunction. Such an interpretation implies, for an ionospheric model, that the predominating core radiation at the millimetre wave-lengths originates from a slightly retrograde rotating planet. The spectral contributions from the mantle and the core of the ionospheric model are shown in Fig. 6.

There are acknowledged objections to the ionospheric model based on the intensity and character of the radar returns from Venus[8]. It is also to be recognized that each model in itself probably oversimplifies a complex environment and that a combination of the elements of the models is required to describe the radiation in detail: certainly the inclusion of water vapour would improve the 'spectral fit' around 20 Gc/s and provide the characteristic of increasing the rate of extinction between 35 Gc/s and 180 Gc/s as exhibited by the median 35-, 70- and 94-Gc/s values.

This work and the continuation of the investigations of millimetre wave-length radiation from bodies of the solar system are supported by a grant *NsG*–432 from the National Aeronautics and Space Administration.

MAGNETIC, GRAVITY AND DEPTH SURVEYS IN THE MEDITERRANEAN AND RED SEA

By T. D. ALLAN
Saclant ASW Research Centre, La Spezia
H. CHARNOCK
National Institute of Oceanography, Wormley, Godalming
AND
C. MORELLI
Osservatorio Geofisico Sperimentale, Trieste

ALTHOUGH a relatively small and land-locked basin, the Mediterranean has many oceanic features. About three-quarters of the area is deeper than 1,000 fathoms, with extensive areas deeper than 1,500 fathoms and isolated depths of more than 2,500 fathoms. The western and eastern basins are geophysically different.

In both western basins there are extensive areas of abyssal plain, whereas the floor of the eastern basin, in spite of the sediment from the Nile, is characterized by an unusual type of small-scale relief. To the north of the eastern basin the Cretan island arc bounds the irregular topography of the Aegean Sea. Geophysical investi-

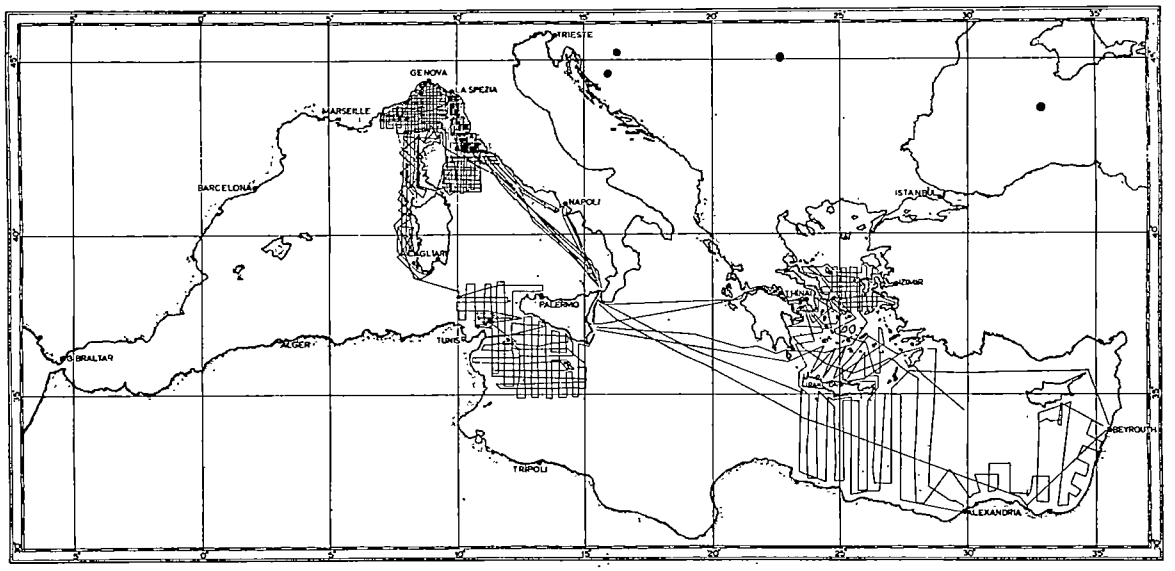

Fig. 1. Tracks of S.S. *Aragonese* in the Mediterranean Sea during the period July 1961–March 1963

gations of the differences between the eastern and western basins may provide clues as to their origin.

The Red Sea is another area where systematic observations may be of more than local interest. Previous observations have shown the similarity between the rift valley of the southern Red Sea and that of the mid-Atlantic Ridge.

The Saclant ASW Research Centre was commissioned in 1959 and its Oceanography Group formed the following year. Submarine geophysical observations in both the Mediterranean and the Red Sea have formed part of the group's programme. A summary of the geophysical work is given in this article.

Facilities

S.S. *Aragonese*, a freighter 293 ft. long, displacing 3,000 tons, was chartered for conversion into a marine research vessel. Radar, gyrocompass, precision depth recorder and other essential equipment were fitted initially. A Loran-*C* receiver and an electromagnetic log were fitted later.

The number of scientific personnel directly involved with the geophysical programme was small and the group frequently co-operated with other research establishments.

An agreement was reached with the Osservatorio Geofisico Sperimentale, Trieste, on a joint programme of gravity, magnetic and bathymetric survey work. The gravity meter, a Graf-Askania, was owned by the Osservatorio and operated by its staff throughout the cruises.

The gravity values were usually tabulated at 15-min intervals. The accuracy of the free-air gravity value depends not only on the performance of the meter and stabilized platform but also on the accuracy of the Eötvös correction which is calculated from the ship's speed and course. In this respect the Mediterranean has presented fewer problems than those in the ocean generally. In the earlier cruises radar signals on numerous islands provided good control: for most of the work the probable error in position was $\pm 0{\cdot}25$ mile. For the later surveys, in areas far from land, Loran-*C* positions proved reliable to better than $\pm 0{\cdot}5$ mile.

The magnetometer was the nuclear spin model described by Hill[1] and manufactured by Bruce Peebles, Ltd. It had a sensitivity of $\pm 0{\cdot}5$ γ. Readings were taken every 30 sec and recorded on punched paper for later reduction on the Centre's computer. The greatest inaccuracy in the measurement of the absolute value of the field lay in the uncertain knowledge of its diurnal variation.

Depth was recorded on a precision depth recorder which could be read to ± 1 fathom.

During the period July 1961–March 1963 seven cruises were made. These were devoted almost entirely to magnetic, gravity and depth surveys of selected areas, but brief trials of other techniques, such as coring and seismic reflexion profiling, were also made.

About 40,000 miles of track have been covered: the distribution in the Mediterranean and Red Sea is shown in Figs. 1 and 2.

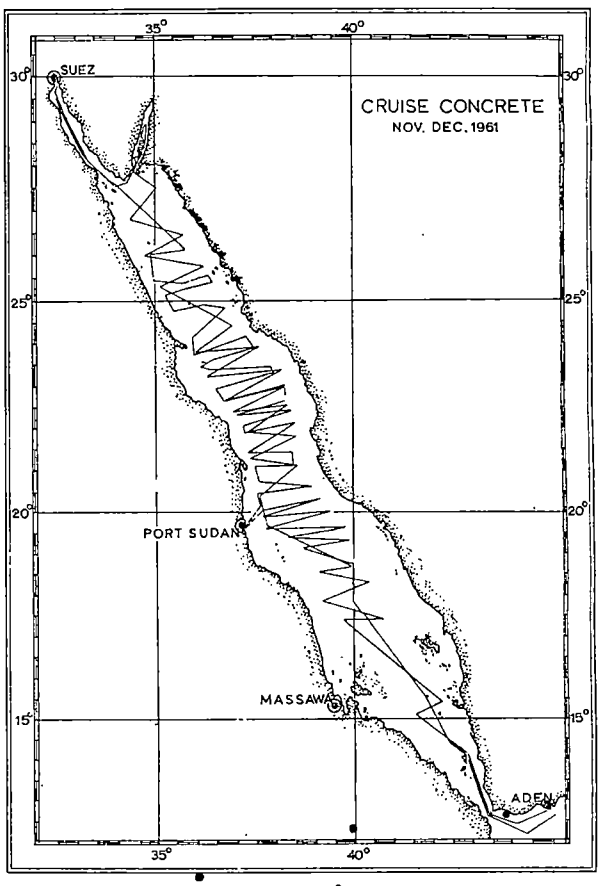

Fig. 2. Tracks of S.S. *Aragonese* in the Red Sea during November–December 1961

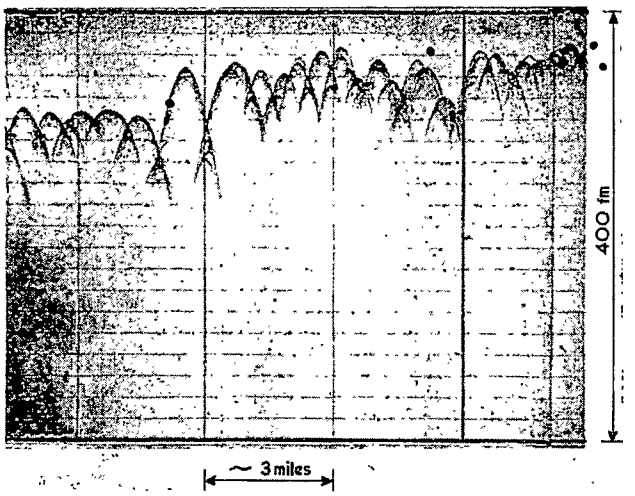

Fig. 3. Profile across the unusual floor of the eastern Mediterranean Sea

Western Mediterranean

The first cruise was used to compare the performance of different types of gravity meter. The Trieste Graf-Askania and a LaCoste-Romberg instrument provided by the U.S. Office of Naval Research were installed in the ship. Observations were made in three areas between La Spezia and Sicily where earlier bottom gravity readings[2] provided a precise reference. Consequently, not only relative but absolute comparisons of the surface-ship meters were possible. In the area near La Spezia precise navigational control was achieved by using theodolites on nearshore hills.

The gravity meters agreed within 10 m.gal in calm conditions, but modifications to the LaCoste-Romberg were necessary to allow for the 'Browne' corrections in rougher weather. An account of the comparisons has been published[3].

Other cruises in the western basin have examined the continental slopes which border the Balearic and Tyrrhenian abyssal plains. These slopes are cut by submarine canyons resembling those found in other parts of the continental margin but which have been interpreted as former sub-aerial valleys.

Between Sicily and Malta the survey did not appear to change the existing conception of the geology of the area. There were large magnetic anomalies around volcanic islands such as Pantelleria, and the negative Bouguer gravity anomaly known to exist in western Sicily was shown to change to a positive anomaly in the centre of the Strait.

Eastern Mediterranean

In the eastern Mediterranean the islands of Crete, Scarpanto and Rhodes appear to form an island arc structure with contrasting geophysical properties in the areas to the north and south of the arc. These areas have been extensively surveyed during three of our cruises. Dr. K. O. Emery took part in one of these, during which a relief map of the sea-floor was prepared from a study of the type of bottom displayed on the echo-sounder.

Much of the sea-floor in the eastern basin is characterized by the type of small-scale relief shown in Fig. 3. The lack of deposition appears to be caused by a series of trenches which border the area and act as a trap for sediment spreading from the Nile.

Perhaps the most interesting aspect of the eastern basin, in spite of the lack of sedimented area, is the dullness of its magnetic field. Thus, apart from the latitudinal variation, there is no significant change of magnetic field between North Africa and Crete. This can be seen from Fig. 4, which shows a typical north south profile of magnetic field, gravity and depth across the island arc. To the north there are several isolated magnetic anomalies, probably associated with vulcanism.

The gravity field is broadly similar to that associated with the island arcs of the major oceans. Generally negative in the southern part of the eastern basin, there is a free air anomaly of about −100 m.gal in a band associated with the deep trenches just to the south of the arc. To the north the gravity field is generally positive, reaching +140 m.gal.

The Red Sea

A survey of the Red Sea and Gulf of Aqaba was made between October and December 1961. A second Graf-Askania gravity meter, supplied and operated by scientists of the German Hydrographic Institute and the Bundesanstalt für Bodenforschung, was embarked for this cruise and provided a good opportunity of comparing the performance of two meters of the same type. Over most of the cruise the agreement was excellent.

Preliminary surveys in the Red Sea[4,5] had shown the existence of a magnetic anomaly associated with a steep-sided medial valley about 30 miles wide. This anomaly was studied in much more detail during the 1961 cruise. A total of fifty-four transverse crossings were made. Records from a typical crossing (20° N.) are shown in Fig. 5.

A preliminary analysis of the results shows that the median valley, which is more fully developed in the south,

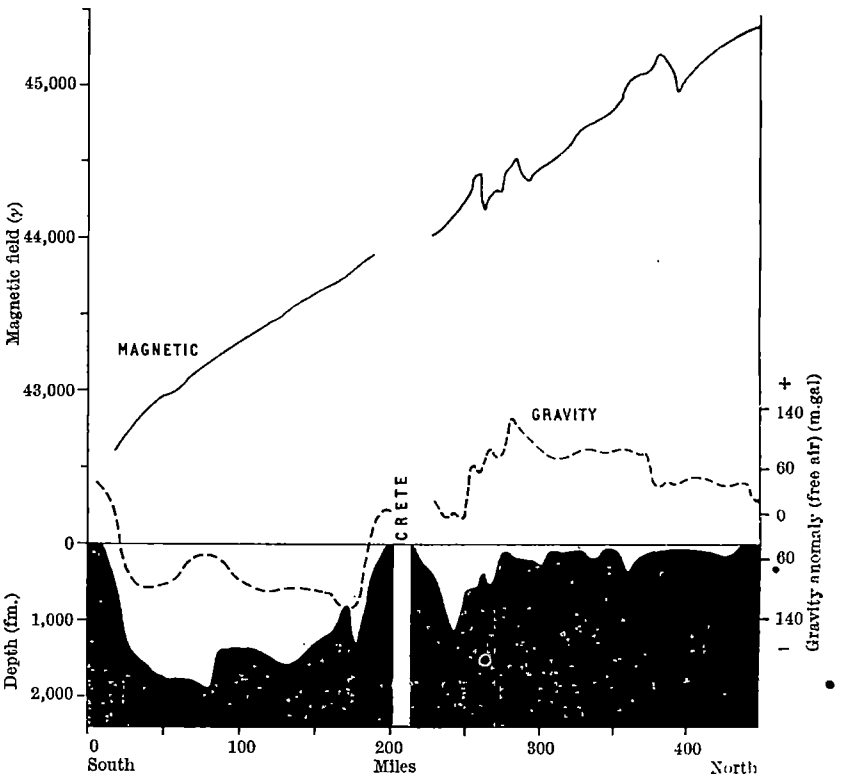

Fig. 4. Profile along meridian 26° E. of gravity (free-air) anomaly, total magnetic field and depth. The southern limit is the African coast and the northern limit lies at latitude 39° N. in the central Aegean

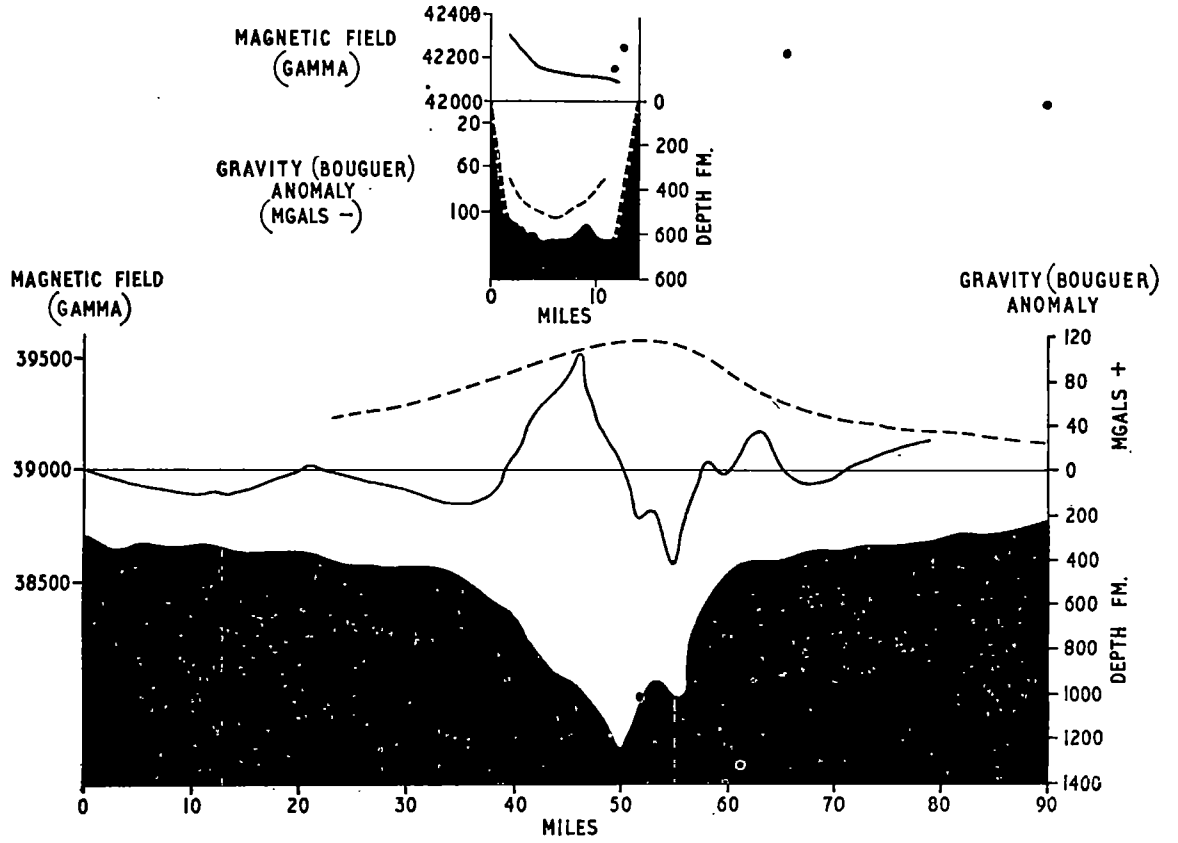

Fig. 5. Gravity and magnetic profiles across the Gulf of Aqaba (top), and across the Red Sea at 20° N. (bottom). The profiles are drawn to the same scale

is underlain by a considerable thickness of dense, magnetic rock. The lateral extent of this material appears to be confined to the width of the valley.

At the northern end of the Red Sea the Gulf of Suez is shallow and dull both in its magnetic and gravity structure. The Gulf of Aqaba, however, provides an interesting contrast. The Aqaba rift is everywhere less than 15 miles wide and about 600 fathoms deep. It is flanked on both sides by steep mountains. There is a strongly negative gravity anomaly, reaching −200 m.gal (free air) and −100 m.gal (Bouguer), while the magnetic field is featureless. The structure of the Gulf of Aqaba resembles that of the Gulf of Corinth; both may be thickly sedimented grabens.

The contrasting geophysical properties of the Gulf of Aqaba and the Red Sea, shown in Fig. 5, must be taken into account in any attempted interpretation of the origins of the Rift system.

We thank Dr. E. T. Booth and Dr. J. M. Ide for their advice during their service as scientific director of the Saclant ASW Research Centre; and our colleagues, ashore and afloat, and the captain, officers and crew of S.S. *Aragonese* for their assistance.

SYNTHESIS OF PYROPHOSPHATE UNDER PRIMITIVE EARTH CONDITIONS

By Prof. STANLEY L. MILLER and MICHAEL PARRIS
Department of Chemistry, University of California, San Diego, La Jolla

It is reasonable to assume that some of the polymerization and dehydration reactions of simple organic compounds on the primitive Earth were carried out by high-energy phosphates. Experiments based on this assumption have been performed by Schramm *et al.*[1], who reported that ethyl metaphosphate can effect a number of polymerizations including the synthesis of polynucleotides from nucleotides. These polymerizations are carried out in anhydrous dimethylformamide as solvent, and they apparently require closely controlled conditions since they are difficult to repeat in detail[2–4]. Ponnamperuma, Sagan and Mariner[5] have synthesized adenosine triphosphate from ADP, AMP or adenosine in dilute aqueous solutions using ethyl metaphosphate and ultra-violet light. The role of the ultra-violet light is not clear, since the ethyl metaphosphate is already a high-energy phosphate.

Ethyl metaphosphate is prepared from phosphorus pentoxide, diethyl ether and chloroform. It is most unlikely that such a polymer could have occurred on the primitive Earth, at least if synthesized in this way. The most unlikely aspect is not so much the diethyl ether or chloroform, but rather the P_2O_5. Phosphorus pentoxide does not occur naturally on the Earth, and if it were

formed by some thermal process it could not be made available for synthetic reactions before it was hydrated by traces of moisture. The occurrence of polyphosphoric acid, which has been used in a 'thermal model of prebiological chemistry'[6-8], is also improbable for similar reasons.

It would be more plausible to assume the presence of meta- or poly-phosphates. These compounds are well known[9] and easily prepared by heating alkali metal or calcium dihydrogen phosphates above ~300°. However, metaphosphate minerals are not known to occur in Nature. This is not surprising since $Ca(H_2PO_4)_2$, which is the starting material for a thermal dehydration to calcium metaphosphate, is itself not a known mineral[9]. Pyrophosphate could be formed by the thermal dehydration of brushite ($CaHPO_4 \cdot 2H_2O$) or monetite ($CaHPO_4$), which are relatively rare minerals, but this apparently does not occur since not a single pyrophosphate mineral is known[10-12].

Although pyro- or meta-phosphate minerals may eventually be discovered, it is clear that they do not occur on an extensive scale. Greater volcanic activity on the primitive Earth would not change this conclusion. The phosphate in igneous and metamorphic rocks, which would be the most likely places to find thermally produced metaphosphates, occurs principally as hydroxyl apatite ($Ca_{10}(PO_4)_6(OH)_2$) with varying degrees of substitution of the hydroxide by fluoride and chloride. The principal phosphorus mineral in sedimentary rocks is also apatite.

The reducing conditions on the primitive Earth would not result in reduced phosphorus compounds to any great extent, since all the lower oxidation states of phosphorus are thermodynamically unstable in an aqueous environment[13]. Schreibersite (Fe_3P) occurs in the iron phase of meteorites; but the phosphorus would be oxidized to phosphate by water.

We have therefore looked for a low-temperature synthesis of pyrophosphate using various compounds with high free energies of hydrolysis that might have occurred on the primitive Earth, and we have found that pyrophosphate can be synthesized by the reaction of cyanate with hydroxyl apatite. Recently, Steinman, Lemmon and Calvin[14] have used cyanamide and its dimer to synthesize glucose-6-phosphate, pyrophosphate and AMP. These dehydration reactions were carried out in dilute solution at a *p*H of 2.

The apatite was prepared by adding 0·04 M sodium dihydrogen phosphate to 0·025 M calcium chloride, both buffered at *p*H 8 with *tris* [*tris*(hydroxymethyl) aminomethane]. The apatite formed was centrifuged and washed several times with water. This apatite was finely divided, and its X-ray powder pattern showed good crystallinity. The apatite was suspended in 0·05 M *tris* buffer (0·09 M in phosphate if dissolved), and the *p*H was adjusted with hydrochloric acid or sodium hydroxide. The Ca^{+2} concentration in solution was brought to 0·01 M with calcium chloride, and the cyanate was added as KNCO. The mixtures were shaken in a water bath at 35° for 20 days to complete the reaction. The apatite and calcium pyrophosphate formed were then dissolved with ethylenediamine tetraacetic acid, and this mixture was chromatographed on 'Dowex 1' (ref. 15). The pyrophosphate in the fractions was hydrolysed, and the phosphate was determined by the Fiske–SubbaRow procedure[16]. The identification of product was confirmed by paper chromatography[17], and by comparing the infrared spectrum with an authentic sample of calcium pyrophosphate.

The yield of pyrophosphate as a function of *p*H with 0·001 M KNCO is shown in Fig. 1. The yields are expressed as moles of pyrophosphate synthesized per mole of cyanate added, and the maximum is 27 per cent at *p*H 6·5. In addition to the pyrophosphate, a small amount of triphosphate (about 5 per cent of the pyrophosphate) was obtained. The yields of pyrophosphate

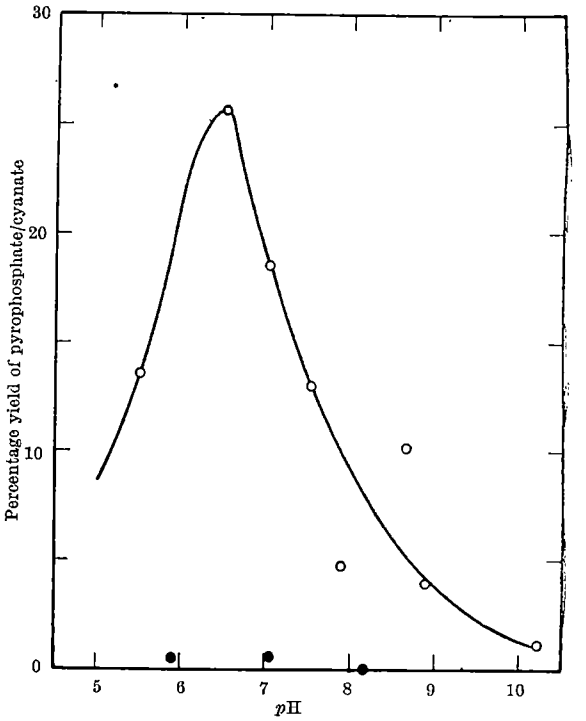

Fig. 1. The yield of pyrophosphate as a function of *p*H. Apatite + 0·001 M KNCO, 0·05 M *tris* buffer (0·1 M borate added for *p*H > 8) (○); 0·64 M sodium phosphate buffer + 0·1 M KNCO (●). Samples shaken at 35° for 20 days

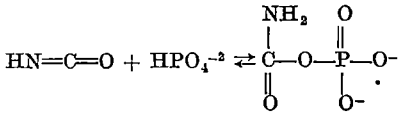
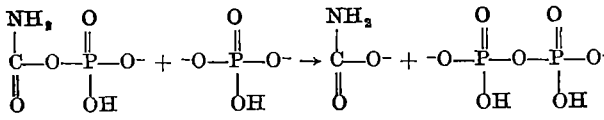
from concentrated phosphate buffers and cyanate are very low (Fig. 1).



Although the synthesis of pyrophosphate is reproducible, there is considerable variation in the yields with the apatite reaction as would be expected with a surface reaction. One preparation of apatite gave lower yields and did not show the *p*H maximum.

The yields with apatite are not affected appreciably by the concentration of Ca^{+2} or by adding Mg^{+2}. Pyrophosphate is also synthesized with apatite prepared in the absence of *tris* and buffered with phosphate. The effect of fluoride, trace elements and various organic compounds on this reaction is being investigated.



The free energy of hydrolysis of cyanate to NH_4^+ and HCO_3^- is about -12 kcal at a *p*H of 8. There are a number of other compounds such as hydrogen cyanide, thiocyanate, cyanamide, and cyanogen which also have a sufficient free energy of hydrolysis to synthesize a pyrophosphate bond and which could have occurred on the primitive Earth. Under the conditions used, hydrogen cyanide, thiocyanate and cyanamide did not react with the apatite to give pyrophosphate. Cyanogen gave significant yields of pyrophosphate with apatite and with soluble phosphate, the yields being greater with the apatite. However, this reaction gives erratic results and is being investigated further.

Cyanate is a reasonable compound to have occurred in the oceans of the primitive Earth. Urea has been synthesized from methane, ammonia and water by electric discharges[18] and by high-energy electrons[19]. The urea in these experiments was probably synthesized from ammonia and cyanate by the Wöhler synthesis. This reaction is reversible[20], $NH_4^+ + NCO^- \rightleftarrows CO(NH_2)_2$, $K_{25°} = 3 \times 10^4$. Although most of the cyanate produced by various sources of energy would react with the NH_4^+ in the oceans, the urea produced thereby would on decomposition yield a low steady-state concentration of cyanate to react with the apatite.

This synthesis could reasonably occur by the reaction of cyanate with phosphate on the surface of the apatite to form carbamyl phosphate:

Carbamyl phosphate ordinarily decomposes back to cyanate and orthophosphate. The equilibrium constant in solution is 3·1 (ref. 21). The reaction of carbamyl phosphate with another phosphate at the O–P bond rather than at the C–O bond would give pyrophosphate by the displacement of carbamate,

The carbamate would then decompose to carbon dioxide and ammonia. These equations refer to reactions taking place on the surface, probably involving chelation by calcium, and the states of ionization have been written arbitrarily.

Jones and Lipmann[21] have proposed that carbamyl phosphate may have been an important source of high-energy phosphate bonds on the primitive Earth. The data here presented support this hypothesis, provided the reaction occurs on the surface of the most abundant phosphate mineral.

It has been pointed out by Gulick[22] and emphasized by Miller and Urey[13] that the synthesis of organic phosphates on the primitive Earth presents difficulties because of the very low solubility of apatite in the ocean (3×10^{-6} M phosphate). The results reported here suggest that a solubilization mechanism for calcium phosphates may not have been needed. The phosphate could have been made available for primitive syntheses by reactions taking place on the surface of phosphate minerals, the concentration mechanism for this relatively non-abundant element being a simple precipitation.

It would appear that pyrophosphate minerals, which are not found on the Earth at the present time, may have occurred in significant amounts on the primitive Earth during the period when the organic compounds leading to the origin of life were being synthesized. This pyrophosphate may have played an important part in polymerization and dehydration reactions of these organic compounds.

This work was supported by U.S. National Science Foundation grant *G*–22000. We thank Prof. G. Arrhenius for obtaining the X-ray powder patterns.

SCIENTIFIC SOCIETIES IN INDIA

By A. RAHMAN, N. SEN and N. R. RAJAGOPAL

Survey and Planning of Scientific Research Unit, Council of Scientific and Industrial Research, New Delhi

RECENT investigations of the sociology of science have suggested a major shift in the organization of science and scientists. The general suggestion is that although science previously was a closed system[1], now it is not so. Science is now a part of society and, as such, is subjected to the same pressures as any other social process[2]. This change, it is contended, has also effected a change in its values. In the period when science was a closed system, as pointed out by Merton[3], its values were centred around the professional recognition of scientists. In this system societies had a major part to play, their transactions published the papers, and these, along with other non-published reports, were discussed in the formal and informal meetings of the societies. This criticism, or appreciation, of the work of fellow scientists built up the reputation of scientists and led to recognition. This process, as Storer mentions[4], suggests that the values of science are rooted in the requirements for continued, adequate allocation of professional recognition rather than in the utilitarian relationship of the value to the aim of science.

With the rapid development of science, and the fact that it has become a large-scale activity, scientific criticism is losing much of its edge[5] and hence professional recognition does not really enjoy the same status as before. In addition, money, prestige and power have come to enjoy greater status than professional recognition[2]. The informal atmosphere has also been replaced by more business-like methods. Greater specialization and the larger number of scientists have also broken the scientific community as of old. What is the impact of these changes on the role of scientific societies? Have societies continued to grow as of old, or have they also undergone changes to meet the new requirements and trends? These questions have great relevance to the growth and development of science.

A number of roles are ascribed to scientific societies, that is, bringing together scientists specialized in the same area of knowledge, affording them an opportunity for intercommunication of ideas within a discipline or between various disciplines through conferences, symposia and publication of journals, serving as a platform for general discussion by scientists of problems of science, and acting as a forum for crystallization of ideas regarding the relation of science to society. They are also supposed to popularize science and confer distinctions on members as a recognition of contributions to science.

No investigation has so far been carried out as to whether these are pertinent roles of scientific societies and how far the various national and international societies are fulfilling these and other related roles. Is there a need to change the role of scientific societies, and in what direction? What are the activities they should undertake and how should they organize themselves? Could there be

various levels of organization according to the needs of specialization and possible social role?

In the context of the growth of science, these questions are very pertinent and, in our opinion, a time has come when we should ask these questions and carry out specific investigations to find the answers.

To fill this lacuna, a survey was conducted by us. The aims of the survey were limited to the collection of data and examining the historical development and activities of the societies and their financial condition. A detailed questionnaire was sent to 150 societies and 115 responded. A directory of the societies was also compiled. The societies were classified as physical sciences, biological sciences, medical sciences, engineering and technology and general societies.

Historical Development

India, before the beginning of the twentieth century, had only four scientific societies, namely, Asiatic Society (1784), Royal Agricultural Horticulture Society of India (1860), Indian Engineering Association (1895), and Bombay Textile and Engineering Association (1900). By the end of the First World War, the total number increased to 16, of which one was physical, three were medical, two biological, six engineering and technological and four general science societies. It is interesting to note that, even though engineering and technology were not very much developed during this period, India had the maximum number of engineering and technological societies, most of which were of a professional nature rather than academic.

Prominent societies founded during 1900–20 were the Indian Association for the Cultivation of Science (1909), Indian Mathematical Society (1907), Indian Science Congress Association (1914), Indian Botanical Society (1920), and Institution of Engineers (1920).

They provided a forum for specialists to discuss academic problems in their fields and also provided scope for scientists of different disciplines to meet to discuss and gain knowledge of the developments occurring in other fields or in border-line disciplines. In fact, in the age of non-specialization in specific areas such general science societies had a special part to play.

The total number of societies increased to 38 by the end of 1940. Between the two World Wars, more specialized societies were founded. During this period, India had four physical, seven medical, five biological, 10 engineering and technological and four general science societies. Most of the non-professional societies, up to this period, used to promote active research work besides providing forums for scientists to meet and discuss; the shift from this activity now becomes noticeable.

Prominent societies which were formed during this period were: Institution of Chemists (1928–29), Indian Academy of Sciences (1934), National Institute of Sciences of India (1935), Indian Physical Society (1939), etc.

During the decade 1941–50, the number almost doubled, the number of societies increasing to 71. The greatest relative increase in societies occurred in the physical sciences group, which increased from four in 1940 to 11 in 1950. The number of medical societies more than doubled, from seven in 1940 to 15 in 1950. Biological science societies increased to 15; engineering and technological societies increased to 10 by the end of 1950.

Independence brought a spurt in the growth of science societies in India. The next decade also saw an equal increase in number. Among those who responded to our questionnaire we find that 33 societies were founded during 1951–60. At the end of 1960, we find that we had 17 physical, 23 medical, 26 biological, 26 engineering and 12 general societies. It is interesting to note that with the increase in specialization in the country the proportion of general societies decreased. Another interesting point is that most of the societies which were established during the 1951–60 decade, in contrast to those established earlier, do not conduct or support scientific research, but only provide facilities for specialists to meet, discuss and cross-fertilize ideas and publish journals or look after the professional interest of members.

Since 1961, the tempo of the growth in number has been slower. During 1961–63, only six societies have been established. Perhaps there may be a few more to which our attention has not yet been directed.

Concentration and Branches of Societies

There is a heavy concentration of scientific societies in the big cities (Calcutta, New Delhi, Bombay, Bangalore and Madras). As many as 118 out of 150 societies are located in these places. Most of the professional societies (in the field of medicine and engineering and technology) have large numbers of branches, but that is not true for other societies. Out of 18 physical science societies, 14 have no branches, and four have 1–5 branches; out of 28 biological science societies, 22 have no branches, three have 1–5 branches, one has 6–10 branches and two have more than 10 branches; out of 15 general science societies, 12 have no branches and three have 1–5 branches. The medical, engineering and technological societies, which have a pronounced professional character, have a large number of branches; for example, out of 26 medical science societies, 12 have no branches, six have 1–5 branches, four have 6–10 branches and four have more than 10 branches. Among the 28 engineering and technological societies, nine have no branches, 11 have 1–5 branches, three have 6–10 branches and five have more than 10 branches.

Membership of Societies

It is significant that the membership in 1962 of professional societies was higher than that of the academic societies. Out of 18 physical science societies, seven had membership below 100, eight had 100–499 and three had more than 500 members. None of the societies had more than 1,000 members.

Out of 25 medical societies whose membership figures are available, four had less than 100 members, 14 between 100 and 499, four between 500 and 999, and three had between 1,000 and 4,000.

Biological science societies usually have a larger membership than physical science societies. Out of 27 (whose data were available), six had less than 100, 16 between 100 and 499, three between 500 and 999, and two between 1,000 and 5,000 members.

It is observed that the membership of engineering and technological societies is heavy, mainly because of their professional nature. The Institution of Engineers is the only society which has more than 5,000 members; in fact, it had more than 42,000 members in 1962. Out of 28 societies in this group, four have fewer than 100 members, 10 between 100 and 500, seven between 500 and 1,000, six between 1,000 and 5,000, and only one more than 5,000.

Membership of general societies is usually limited to 100–500 members. Out of 16 such societies whose membership figures were available for the year 1962, 13 have membership between 100 and 500, two between 500 and 1,000, and one (Indian Science Congress Association) had a total membership of 4,683.

Mode of Becoming Members of Societies

There is not much group difference here. The common mode is by election and payment of subscription. Out of 115 who have reported, in 48 societies, membership is through paying a fee, in 52 through election and payment of fee, in four by election only; in eight engineering, two physical and one medical science societies, one can become a member by passing examinations conducted by the society.

Only 16 out of 115 societies conduct examinations, and, of these, 10 are engineering and technological societies,

two physical, one medical, two biological societies and one general science society.

Activities of the Societies

The societies which conduct examinations also provide library facilities. About 50 per cent of the societies confer some kind of honour, by way of award of a gold medal, cash prize or membership or fellowship, to their members.

About 88 per cent of the societies publish one or more journals; in all, out of 115 societies which replied, 101 publish 123 journals. The details are as follows:

Out of 18 physical science societies, 15 publish journals and they publish 19 journals in all; out of 26 medical societies, 21 publish 24 journals; out of 28 biological societies, 26 publish journals and they bring out 32 journals; out of 28 engineering and technological societies, 26 publish 33 journals; and out of 15 in the 'general' group, 13 publish 15 journals.

It is interesting to note that 49 out of 115 societies had not conducted any symposium, seminar or conference during the past 10 years. Out of 66 who arranged any of the aforementioned meets, scarcely 20 per cent did so as an annual feature; many of them do meet a number of times in a year but only to conduct the business of the society. This may suggest that societies are playing a limited part in the promotion of science, and that only through publishing journals. They give little opportunity to members to discuss specific research topics or academic problems.

Financial Support

Our investigation reveals that, in all, only 41 societies get direct or indirect support from the Central Government, 35 societies get little financial support from State Governments, 21 societies get support from industry and 16 from endowment funds. It is interesting to note that those who receive support from Central or State Governments also get support from other sources. Of those who receive support from the Central Government, many of them get support from State Governments also. The support which is available mostly goes to a selected few societies, while the rest depend solely on their own resources. Seventy-five per cent of the funds which come from Central or State Governments are distributed to a few of the societies, with the result that funds for most of the others are not enough even to run their journals, let alone arranging seminars or symposia at an all-India level, which usually demands heavy expenditure.

This investigation reveals the following features:

(1) Growth of scientific societies has kept pace with that of science and technology.

(2) General and professional societies (that is, engineering and medical) were founded earlier and were followed by more specialized societies. Recent trends have been towards the establishment of more sophisticated societies in the newly developing fields of science and technology like Operations Research Society of India, Institute of Information Scientists (of India).

(3) Societies are mostly concentrated in the big cities of Calcutta, Bombay, Madras, Delhi and Bangalore. This is in keeping with the concentration of scientific research institutes in large cities. It may be observed here that most of the earlier academic type of scientific societies were founded in the Calcutta region. In recent years, however, new societies are being formed at a faster rate in the Delhi and Bombay regions.

(4) Earlier societies of the academic type were mostly institutional in nature, that is, as a part of their activity they not only provided a forum for scientists to meet, arrange symposia and publish journals, but also they encouraged scientific research or carried out research as a part of their activity. The last-named activity is not a feature of the more recent societies.

(5) Professional societies in the field of engineering, technology and medicine have usually a larger number of branches and members. Specialized societies in more academic fields have usually smaller membership. The increase in membership of the more academic type of societies is not in keeping with the rise in number of research workers in those fields.

(6) Most of the societies do not receive any support from the Government, either Central or State. Those who receive from one source, receive from others also. Whatever support is available from the Government, most of it goes to a few. Many of the societies are publishing journals from their own resources, in view of their limited finance, and the standard and regularity in publishing the journals suffer. It is of interest to note that most of the support from Government goes to the more academic type of societies rather than to professional engineering and medical ones.

(7) The most curious feature is the lack of activity of societies by way of organizing academic activities, namely, symposia, seminars and specialized discussions. This may be due to the lack of financial resources available to them, as against the established institutions*.

Two major conclusions could be drawn from this work: one for India and the other more generalized. For India, the conclusions are the need for critical examination of the activities of the societies and the support they are receiving from the Government. There is an urgent need for the developing of a proper policy for support of scientific societies, particularly for those which cover the newer fields of science and technology and those which deal with the social problems of science or with science as a whole.

It is suggested that the Government should not only finance the academic societies to arrange the seminars and symposia but should also make sufficient provision in the budget of the research institutes to enable active research scientists to attend seminars or symposia, organized by the societies. Finally, there is also a need for associating the scientific societies in forming decisions. This is vital for the healthy growth of science, and its democratization in India where most of the decisions are taken by a discrete group. This would not only add to the prestige of the societies but would also enable them to become alive and take an active part in the promotion of their field of specialization and science as a whole.

The more generalized conclusions are with regard to the role of specialized societies in giving direction to research in their field of interest. At the moment the quantum of information and the nature of symposia are such that at no place could a critical appreciation of the trends of research in a particular field be made. This requires immediate attention. Secondly, with the growth of greater degrees of specialization in science, there is a need for more generalized discussions, where more than one discipline could be integrated and where problems of policy, planning and other social aspects of science could be discussed. To have a specialized society for such discussion would not serve the purpose. What is needed is the participation of scientists from different fields of specialization to take a synoptic view of science and contribute to such generalized problems, which means a greater emphasis on general societies.

Finally, there is a need to re-examine some of the traditional activities, the impact they are creating and the efficiency with which they are fulfilling their objectives.

In the light of such an analysis and the trends in science, the need for re-orienting the activities of societies might emerge.

* It appears from the historical records that the work of earlier societies had greater impact on India of their day, though the standard of work and publication appears higher to-day.

OBITUARIES

Sir James McNeill, K.C.V.O., C.B.E., F.R.S.

JAMES MCFADYEN MCNEILL, who died on July 24, was born in 1892, at Clydebank, where, in 1870, the establishment of a shipyard and engine works had led to the foundation of a burgh. His schooling was first local, and then in Glasgow at Allan Glen's, a school notable for the opportunity offered to aspirants toward engineering. His father was a foreman in the shipyard of John Brown and Co., and in 1908 James McNeill began an apprenticeship there, and an association which, with only a war-time interruption, was to be continuous. In those days, a technical education was a luxury which had to follow a normal apprenticeship, and it was not until 1912 that James McNeill, with a good knowledge of shipbuilding as a background, matriculated at the University of Glasgow. In 1915 he graduated as B.Sc., the leading student of naval architecture in his group, winner of prizes in engineering and in mathematics as well as in his own specialized subject, and, withal, quiet and unassuming; an indication of another interest was attendance at the class of political economy. Graduation was soon followed by enlistment, with the Royal Artillery as the choice. In the German offensive of early 1918 the conduct of Captain James McNeill as a battery commander gained for him a mention in despatches, a Military Cross, and promotion to field rank.

Back to the shipyard after the War, James McNeill was placed in charge of the design and technical section associated with the ship drawing office. It was fairly soon apparent that in the years of war there had been marked development of latent qualities—acceptance of responsibility and exercise of leadership. The development was recognized when, in 1928, following an unexpected vacancy, the young man was appointed naval architect to the Company, a position carrying responsibility for the preparation of all shipyard plans, from the design stage onwards to completion, and leading in a few years to a seat on the local board of directors. The first major work carried out by James McNeill was the design and completion of the *Empress of Britain*, the largest ship built in Great Britain since the completion of the *Aquitania* in 1914; there had been keen competition for the contract, and there were stringent conditions to be fulfilled. In the launching of this large ship a feature new in Britain was the use of ciné cameras, and the painting of 'register' marks on the hull, in order that a complete and reliable record could be obtained of the travel of the ship down the launching ways and, especially, of the 'plunge' as the fore end of the launching cradle dropped off the end of the ways; the placing of some of the cameras involved some of the technique of the skilled gunner.

The record of the launching of the *Empress of Britain* was valuable in itself. There was, however, special intent behind it. Consideration was already being given to the problem of building and launching a ship about 1,000 ft. long, and the cost of the dredging necessary to permit the launching into a restricted river was a factor to be taken into account. From the records of the launch of the *Empress of Britain* it was found that the dredging need not be so extensive as had been feared. The successful launching of the *Queen Mary* in 1934 was, in a way, a development from the launching of the *Empress of Britain*. There was also, however, much fresh and patient investigation of the whole range of problems involved in what is at once a crude and a highly complicated operation. A comprehensive record of the investigations and of the treatment of the problems was presented to the Institution of Naval Architects in 1935 in a paper by Mr. McNeill which is a masterpiece.

The patient and perceptive thoroughness which Mr. McNeill had displayed in his first major work for John Brown and Co. was carried on throughout his career in the shipyard. The range of his activity was wide, and although the *Queen Mary* and *Queen Elizabeth* are his masterpieces, he left his mark on lesser-known craft of all types. In 1948 he became managing director of the establishment to which he had come as an apprentice forty years before: and then in 1953 he became deputy chairman of the Company, a position he held until retirement in 1962. A catalogue of honours includes first the honorary degree of LL.D. from the University of Glasgow in 1939, election as a Fellow of the Royal Society in 1948, Royal appointment as C.B.E. in 1950, and as K.C.V.O. in 1954. Appreciation of colleagues in the shipbuilding and engineering industry was shown by selection for high office in the ancillary organizations of the industry, and in the professional institutions.

In Sir James McNeill there was much more than technical capacity. There was staunch integrity, allied to wisdom and kindliness, qualities which won the respect of all who were concerned with ships produced at Clydebank, whether as owners of ships or as officers of Government. With a streak of the puritan in him, he could come down hard on any tendency toward vulgarity in the conversation across the shipyard lunch-table. He could express strong dislike of income tax 'fiddling', and also of bullying of juniors—to him, bullying was the resort of the man who was not up to his job. A. M. ROBB

Prof. Louis Fage

THE well-known French zoologist, Louis Fage, member of the Académie des Sciences, Commandeur de la Légion d'Honneur, died in Dijon on May 28, in his eighty-first year. Formerly professor at the Muséum National d'Histoire Naturelle, Paris, and at the Institut Océanographique, he was outstanding as investigator, lecturer and administrator. His publications include the volumes on Amphipoda (with Chevreux, 1925) and Cumacea (1951) in the *Faune de France*, and the sections on Merostomata and Pycnogonida in Grassé's *Traité de Zoologie* (1949).

He was born on September 30, 1883, in Limoges (Haut-Vienne), France, son of René Fage, barrister and corresponding member of the Académie des Inscriptions et Belles-Lettres. He was educated at the Collège St. Martial, Limoges, and entered the University of Paris in 1900, still undecided as to his course of study. It so happened that Gaston Bonnier and Edmond Perrier were old family friends; on their advice he chose the natural sciences and obtained his doctorate in 1906. Forty years later Goodrich referred to his thesis on the segmental organs of polychæte worms as the most important of the general works on nephridia and allied subjects which had appeared since 1895.

For the next fourteen years he served as naturalist to the Service Scientifique des Pêches Maritimes, attached to the Laboratoire Arago, Banyuls, of which Racovitza was the resident deputy director. His work on Mediterranean fishes attracted the attention of the oceanographer, Johannes Schmidt, and led to a life-long association with Danish scientists. He found the local methods of catching pelagic shoaling fishes rudimentary in the extreme and suggested fishing with lights at night. He also used this method extensively for the collection of plankton; this work, started in the Mediterranean,

was continued over a period of years at Concarneau with Legendre and greatly extended our knowledge of the biology of many littoral invertebrates. During this period he also became interested in Arachnida and in speleology. He joined Racovitza and Jeannel, founders of the association known as Biospeologica, in their explorations and described the cavernicolous spiders. This had an interesting sequel; in 1947 Fage put the case for a subterranean research laboratory to the director of the Centre National de la Recherche Scientifique (C.N.R.S.) so successfully that soon afterwards the laboratory at Moulis (Ariège) was opened.

The year 1920 marked a turning point in Fage's scientific career. At the invitation of Charles Gravier he joined the staff of the Muséum National d'Histoire Naturelle, Paris, as deputy director of the zoological laboratory, in charge of various invertebrate phyla. He became director of the laboratory in 1938, a post he held conjointly with his professorships until his retirement in 1953. To commemorate his scientific jubilee he was presented just after his seventieth birthday with a gold medal specially designed by Robert Cochet.

Fage also played a prominent part in scientific activities outside the Museum and outside France. For example, during 1924–27 he was secretary of the Société de Biogéographie, of which he was a founder member. He was president of the Société zoologique (1929), the Société entomologique (1935) and the Académie des Sciences (1955). He was secretary-general of the Permanent Committee of the International Congresses of Zoology (1948–53) and represented the Institut Océanographique on the Conseil International pour l'Exploration de la Mer, the Commission pour l'Exploration de la Mediterranée and the Commission internationale d'Océanographie. A member of the C.N.R.S., he was chairman of the Bathyscaphe-Calypso Committee and of the Moulis Laboratory Committee. For many years he was editor or co-editor of various periodicals such as the *Archives de Zoologie expérimentale et générale* and the *Annales de l'Institut Océanographique*; he was a co-editor of *Deep Sea Research* from its inception in 1953.

Over a period of almost sixty years Fage published some 250 scientific papers, monographs and books dealing with many quite unrelated groups of animals from Protozoa to fishes. Although much of his museum work was of necessity taxonomic, he was pre-eminently a field naturalist interested in the living animals, their habits, habitats and life-histories, their geographical distribution in relation to environmental factors, their evolution. An authority on Arachnida, he described the habits of spiders that lead an amphibious life among tropical corals or the encrusting calcareous algal growths (the 'trottoir') of Mediterranean shores, that live normally in the urns of pitcher plants or as commensals in the nests of ants and termites. He studied the development, metamorphosis, growth, spawning and migrations of many coastal fishes, and applied biometric methods to the elucidation of the different races of sardine and anchovy. He found that many bottom-living invertebrates, especially annelids, cumaceans, amphipods, mysids and sea-spiders, have pelagic phases which are subject to nycthemeral, lunar and seasonal rhythms, and that many supposedly rare sedentary species may be captured in thousands at certain times. His *Dana Reports* on the primitive mysidacean order Lophogastrida (1941) and (1942) and on the pelagic amphipod family Oxycephalidae (1960) deserve special mention. The vast amount of material (for example, *Gnathophausia* 875, *Ceratolepis* 174 and oxycephalids 35,000 specimens), available for the first time, enabled him to add much to our knowledge of the systematics, chorology, sexuality and parasites of the species represented. In the field of oceanography he investigated the influence of the organic content of marine sediments on the distribution and density of the abyssal benthic fauna; also the variation in the amount of oxygen dissolved in the sea-water immediately above the sediments. For an account of Fage as speleologist the reader is referred to Prof. Vandel's obituary note in *Annales de Spéléologie* (19 (2), 245; 1964).

Fage was a foreign member of many scientific societies, including the Zoological and Linnean Societies of London. Of the many honours which were conferred on him, he must, one imagines, have valued highly the gold medal of the Johannes Schmidt Foundation for the Exploration of the Sea (1958). All this notwithstanding, he was without ostentation, modest, sincere and kind, at his charming best when entertaining a few friends in his own home. His wife, *née* Marie Marguerite Gigaud-Lafont, predeceased him by about three years; they had one son and one daughter.

Isabella Gordon

NEWS and VIEWS

The Royal Society : S. G. Brown Medal and Award

In January 1964 the Council of the Royal Society announced the establishment of a fund, following a bequest under the will of the late S. G. Brown, the income from which would be used to offer annually an S. G. Brown Award and Medal for an outstanding contribution, based on work carried out during the preceding five years, to the promotion and development of mechanical inventions (*Nature*, 201, 556; 1964). Recommendations for the award were to be made to the Council by the Councils of the Institutions of Civil, Mechanical and Electrical Engineers in rotation. It has now been announced that the first award has been made to Mr. F. M. Adler a civil engineer, for his work in the promotion and development of the 'Jackblock' technique, a system for the construction of tall buildings providing factory conditions during erection. The roof is constructed first, at ground level, and then raised by jacks for the top-most floor to be constructed beneath it, and so on. During the process each floor travels vertically through a 'factory' in which all the services, fittings and finishes are installed. A 17-storey block of flats has recently been completed at Coventry using this technique.

Biochemistry in University College, Dublin : Prof. E. J. Conway, F.R.S.

Prof. E. J. Conway retired from the chair of biochemistry and pharmacology in University College, Dublin, on October 29. After a brilliant undergraduate career in that University, he graduated in science in 1916 and in medicine in 1921. There followed a vigorous research programme on renal physiology in the Physiology Department under Prof. J. M. O'Connor on the basis of which he was awarded the D.Sc. degree in 1927. As a Rockefeller Fellow he worked for two years with Embden at Frankfurt. On returning to Dublin he was appointed to the chair of biochemistry and pharmacology in 1932. During the thirty-two years that he occupied the chair, Prof. Conway published two books and more than 150 research papers, monographs and review articles. In addition to his earlier work on renal physiology, he is well known internationally for his contributions to the mechanisms of electrolyte exchanges between cells and their environment, the evolutionary origins of such environments, the mechanism of gastric acid secretion and the technique of microdiffusion analysis. His outstanding place in world science can best be assessed in terms of the honours which

have been bestowed on him. Chronologically, the most important of these include: fellowship of the Royal Society (1947); fellowship of the Royal Society of Arts (1952); membership of the Académie Septentrionale, Paris (1961); membership of the Pontifical Academy of Sciences (1961); honorary fellowship of the Royal Institute of Chemistry (1963); fellowship of the Institute of Biology (1964). In 1960 he was appointed chairman of the Institute for Advanced Studies in Dublin. In 1960 the Irish Government made a special grant to institute a Unit of Cell Metabolism under his directorship as part of the Medical Research Council of Ireland. Now, as he leaves the chair to which he has brought such honour, it is to be hoped that in these two capacities his active research programmes will continue, and his advice and encouragement will continue to be available to the younger generations of Irish biochemists.

Prof. M. G. Harrington

Dr. M. G. Harrington, lecturer in biochemistry in University College, Dublin, has been appointed to the chair of biochemistry in succession to Prof. Conway. A graduate in science of University College, Cork, Dr. Harrington was in 1952 awarded the travelling studentship in biochemistry of the National University of Ireland during the tenure of which he carried out, in association with Prof. E. F. Gale at Cambridge, investigations of the action of antibiotics on Gram-negative organisms. In 1954 he was appointed to the Department of Biochemistry and Pharmacology in Dublin, becoming lecturer in biochemistry in 1958. From 1954 until 1963 he worked in collaboration with Prof. Conway on various aspects of electrolyte physiology; in particular, investigations of the uptake of sodium by frog sartorii, and the application of electron microscopy to such investigations. During 1963–64 he was visiting associate professor of physiology at Tufts University School of Medicine, Boston, where he carried out investigations on the fate of chromium-labelled proteins injected intravenously in mice.

Microbiology in the University of Birmingham : Prof. H. Smith

Dr. H. Smith, at present head of chemical pathology at the Microbiological Research Establishment, Porton, has been appointed to the chair of microbiology in the University of Birmingham, as from January 1, 1965, in succession to Prof. D. G. Catcheside, who has been appointed to the chair of genetics within the John Curtin School of Medical Research, the Australian National University, Canberra (*Nature*, 199, 536; 1963). Dr. Smith graduated in the University of London in 1942 and then spent three years with Boots Pure Drug Co. After a brief period as an assistant lecturer in the Department of Chemistry at University College, Nottingham, he moved in 1947 to the Microbiological Research Establishment, Porton. During the past seventeen years he has been concerned with various aspects of microbiology, but his most outstanding work has been concerned with the chemistry of microbial virulence. Dr. Smith is a prominent member of the Society for General Microbiology, and has been a member of its Council since 1960.

Deputy Director, Water Research Association: Dr. E. Potter

Dr. E. Potter has been appointed to the newly established post of deputy director of the Water Research Association. Dr. Potter, who is forty-one, is a graduate of the University of London, having taken the special chemistry degree by part-time study in 1944. In 1940 he joined the Metal Box Co., where he was engaged on packaging problems, and in 1947 entered the Imperial College of Science and Technology. There he carried out research on electrochemical kinetics, gaining his Ph.D. in 1950. Following this, he returned to applied science and, after a year at the Paint Research Station, Teddington, he joined the then British Electricity Authority to set up a research unit for the investigation of corrosion and water chemistry in steam power plant. During the next decade his team achieved fundamental advances in this field, applying them to the practice of large-scale steam generation. His procedure for the analysis of oxygen dissolved in water, for example, is sensitive to one part in five thousand million, and by means of it the oxidation of boiler steel in high-temperature water could be clarified in practical detail for the first time. He received the Beilby Memorial Award in 1957 for these and similar developments. In 1963 Dr. Potter lectured in Australia and New Zealand, and has made many other technical visits, notably to the United States and the U.S.S.R.

Science in Parliament : Aircraft Industry

In a statement to the House of Commons on December 9, the Minister of Aviation, Mr. R. Jenkins, announced that Lord Plowden had accepted the Government's invitation to serve as chairman of a committee to consider the future place and organization of the aircraft industry in relation to the general economy of Britain. The committee would take into account the demands of national defence, export prospects, the comparable industries of other countries and the relation of the industry with Government activities in aviation, and would make recommendations on any steps and measures necessary. The members of the committee would include Mr. Aubrey Jones, Mr. A. Albu, Mr. D. H. Barran, Mr. F. Hayday, Admiral of the Fleet Sir Caspar John, Mr. C. McMahon and Sir William Penney, with Mr. N. Craig as secretary. In reply to questions Mr. Jenkins said that the committee would review the whole field of the aero-space industry, and its deliberations would not postpone decisions on projects already under review. It did not replace the Transport Aircraft Requirements Committee. A similar statement was made in the House of Lords by Lord Shackleton, who added, in reply to a question, that as full an account of the committee's report would be published as matters of national security and commercial confidence allowed.

Manpower Research Unit

In reply to a question in the House of Commons on December 7, the Minister of Labour, Mr. R. J. Gunter, said that the future programme of the Manpower Research Unit would include full consideration of the effects of automation on manpower: he would himself keep under review the need for further work on the effects of human relations in industry. The Unit was exploring the possibilities of manpower forecasts on the basis of the estimated trends in output and productivity, including the effects of automation. Moreover, it was planning to follow its current studies of changes in the occupational structure of the metal industry and the effect of computers on office employment with new studies of the changing structure of particular industries, and on the introduction of particular new techniques.

Solway Barrage

In reply to a question in the House of Commons on December 9, the Minister of State for Scotland, Mr. G. Willis, said that a preliminary examination had already been made of the Solway Barrage proposals. The new step was for the new planning machinery to examine the project, along with similar proposals for Morecambe Bay, in the context of the very substantial and competing claims on the nation's capital investment resources over the coming year. The Scottish Development Group had already had discussions with local authorities on both sides of the Border and also with the North West Study Group on this matter, as well as discussions with Dr. R. L. Drew and experts from the University of Strathclyde.

These had established the fact that the feasibility of impounding fresh water in the way proposed required a further technical survey, and this very considerable undertaking would be considered in due course.

Poisonous Substances used in Agriculture

In reply to a question in the House of Lords on December 2, the Minister of State for Education and Science, Lord Bowden, said that the Government had accepted the recommendations of the Cook Committee on Poisonous Substances used in Agriculture and Food Storage. As assurances had been received of the co-operation of all interests concerned, it had been decided to give effect to the recommendations through the present voluntary scheme. The Cook Committee was now examining the present voluntary safety arrangements, and the need for legislation would be considered in the light of its advice. The Earl of Haddington, Lord Douglas of Barlock and Lord Saltoun all protested that voluntary action was unlikely to be effective and referred to the serious side effects on the breeding of birds, particularly birds of prey. However, Lord Bowden, in view of the agricultural value of these pesticides, merely emphasized that the Cook Committee and the manufacturers were anxious to produce insecticides which had the desired effects with as few side effects as possible. This was the subject of earnest discussion and research. In a written answer in the House of Commons on the same day, the Minister of Agriculture, Fisheries and Food, Mr. F. Peart, stated that investigations by his Department supported the view of the Cook Committee in the review of the persistent organo-chlorine pesticides, published in March 1964, that the restrictions placed on the use of aldrin and dieldrin in cereal seed dressings were serving their purpose and had greatly reduced the number of deaths of seed-eating birds through these chemicals.

Long-term Role of Nuclear Energy in Western Europe

The European Nuclear Energy Agency of the Organization for Economic Co-operation and Development is to carry out a special study of the long-term role of nuclear energy in Western Europe. The study will include evaluations of reserves of uranium and thorium available to European member countries in various cost ranges, of long-term energy demands, and of the likely contribution from nuclear energy towards meeting these demands under the technical and economic conditions which may be expected to develop. The decision to make this study was taken by the Agency's Steering Committee at a recent meeting in Paris, under the chairmanship of Prof. Urs Hochstrasser, Swiss Federal Delegate for Atomic Energy Questions, and results from a preliminary proposal of Prof. Lew Kowarski, the Agency's scientific adviser, which was first discussed by the Steering Committee last July and has since been elaborated by a group of experts from Austria, France, the German Federal Republic, Sweden and the United Kingdom under the chairmanship of Prof. Kowarski. The study is expected to be completed by the summer of 1966.

Occupational Health Service in Dundee

Four years ago the Nuffield Foundation decided to spend a certain sum on experimental group occupational health services to well-established older industries spread over a city or town and mixed with residential and other property. The professor of public health and social medicine in St. Andrews University and the district factory inspector aroused interest and enthusiasm for a group service among prominent business men in the city of Dundee. Dundee's claim as a suitable area was put forward by them and was accepted by the Nuffield Foundation in 1962. This was the beginning of the Dundee and District Occupational Health Service, the progress of which is described by the nursing superintendent, Miss Elizabeth J. Tyren, in *Occupational Health*, 16, July–August 1964.

There are several reasons why Dundee was considered a suitable area for this experiment. It is a medium-sized city of about 190,000 people, contained in an area about five miles by three miles, and is the third-largest city in Scotland. The city stands on the north shore of the Firth of Tay, linked with Fife to the south by a fine rail bridge and the new road bridge.

Dundee has variety in industry, although there are still many people employed in the jute trade. The other industries include linoleum manufacture, light engineering, carpet manufacture, confectionery, and flax spinning and weaving, and the city is a potentially prosperous one. These industries are scattered throughout the area among residential and other property, although an industrial estate is gradually taking shape to the north-west of the city. The member firms of Dundee and District Occupational Health Service are mostly of medium and small size and are, therefore, probably representative of the factories of Great Britain as a whole. The outlying parts of the city are gradually being filled with new houses as the centre of Dundee is replanned and rebuilt.

Another reason for the choice of Dundee was the fact that it is a university city containing the Queen's College of the University of St. Andrews. It was planned that, should the city be accepted for the group experiment, the student health service for Queen's College would become a member of the occupational health service, and this was an added attraction, as no other group health service has a university among its members.

The aims of the service were formulated early and are gradually being fulfilled in the various factories. They are: to promote and maintain the health and safety of people at work; to assist in the provision at work of immediate treatment for sick and injured people; to advise on the rehabilitation and placement in suitable work of those temporarily or permanently disabled by illness or injury; to advise on the provision of safe and healthy conditions by informed scientific assessment of the working environment; to educate all concerned in the attainment and preservation of good health; to carry out or promote research into the causes of occupational diseases and injury, and into the means of their prevention.

Publications of the Medical Research Council

Under the title *Current Medical Research*, the Medical Research Council, following its usual practice, has reprinted articles which appeared in the Report of the Council for the year 1962–63 (Pp. iii+51+3 plates. London: H.M. Stationery Office, 1964. 4*s*. 6*d*. net). An important feature this year is the statement by the Council on the responsibility of investigators who conduct experiments on human subjects. The other articles deal with: the theoretical basis of organ transplantation; damage to human chromosomes due to ionizing radiations; clinical genetics; recent work on the control of ovarian function; the drug-resistances of micro-organisms; the chemotherapy of cancer; protein turnover in the central nervous system; and epidemiological research in psychiatry.

Housing Problems

Public Health Papers, published by the World Health Organization, provide a medium for the publication of reports usually prepared as contributions by the Organization to a particular health question, which have been considered to be of interest to a wider circle of readers than that for which the papers were originally written. *Public Health Paper No. 25* is entitled "Housing Programmes—the Role of Public Health Agencies" (By A. Andrzejewski and seven other authors. Pp. 197. Geneva: World Health Organization; London: H.M. Stationery Office, 1964. 8 Sw. francs; 13*s*. 4*d*.; 2.75 dollars). It discusses the responsibility of public health administrations in the field of housing; the basic principles of housing hygiene in

the U.S.S.R.; the planning of housing programmes; the participation of the community in housing and environmental hygiene in Ceylon; and economic and financial problems associated with housing.

Procter and Gamble, Ltd.

PROCTER AND GAMBLE, LTD., with world-wide ramifications, but operating in Britain at Gosforth, Newcastle upon Tyne, manufactures a large variety of products, of which perhaps the most familiar in domestic circles are many well-known brands of detergents popular with the housewife and others. Other products include edible materials for the bakery trade, industrial soaps, textile brands, air entraining agents and mortar plasticizers, refined and hardened edible oils, soap for emulsifying raw materials in synthetic rubber manufacture, glycerine, fat additives for animal feeds, etc. In the *Financial Statement* for the year ended June 30, 1964, apart from the commendably summarized profit and loss and balance sheet figures, a considerable amount of space is devoted to the aims and activities of this organization, not only in meeting present-day retail demands, but also in being 'one step ahead' by both technical and economic research, to discount the future (Pp. 16. Newcastle upon Tyne: Procter and Gamble, Ltd., 1964). The stress is on 'innovation and change'. "Product Innovation results from the effort to provide better goods; Operational Change from the search for better methods. In the competitive fields in which our company operates, we have to seek both those things continuously. Over the years it is not just the health of the company but its survival that depends on our ability to serve the consumer with better products more efficiently produced." There is a great deal of sound common sense, quite apart from business acumen, disclosed in this booklet; it is a pleasure to read an annual *Statement* which breaks away from many of the cut-and-dried documents conventionally issued to shareholders and others concerned. In this case, that pleasure is enhanced by the inclusion of some beautiful illustrations of Newcastle and Northumberland scenes in colour, the work of David Knight. This modest and artistic approach to the public, devoid of all the usual photographs of factories, plant and people, is in itself quite sufficient advertisement, a model which could well be emulated by some of the larger industrial groups in Britain.

Personnel Management

THE control and welfare of workers in industry, whether in the open air or under cover, in agriculture, civil service, factory, office or shop, have in recent years become the province of people specially trained and selected to take care of the humanities of mass employment such as is experienced to-day in Britain. The qualifications are essentially 'A-levels' at least in practical knowledge of the work concerned, whatever and wherever it may be, and, perhaps at even higher rating, the psychological effects of administration and environment on both men and women. The issues affect everyone, the 'small man', the business executive, and the boards of major industrial and nationalized concerns. It may not be generally recognized that to co-ordinate, organize and publicize much of this important relationship between employers and employees, there exists the Institute of Personnel Management (80 Fetter Lane, London, E.C.4), whose quarterly publication, *Personnel Management*, always reflects the public interest in this subject. Quite a number of people have not fully appreciated the impetus of recent legislation on the new legal status of the average employee, quite apart from mandatory improvements in the conditions under which he or she works. An article by J. E. Genders entitled "The Contracts of Employment Act: A Challenge" (*Personnel Management*, 46, No. 369, September 1964) directs attention to the implications of at least this phase of the problem of industrial humanities. Great changes in the deployment of manpower are inevitable in the near future, under the pressure of advances in automation, which none can stop. As Mr. Genders rightly says: ". . . the achievement of the . . . Act may lie not nearly so much in what it itself lays down, but in the incentive it offers for proper attention to be focused to-day on security of employment in order to provide the right conditions for mobility of employment to-morrow".

Sulphur Dioxide as an Air Pollutant

ONE of the most widespread and dangerous constituents of atmospheric pollution, especially in and around heavily industrialized areas, is sulphur dioxide, derived principally from the combustion of various fuels, for example, coal and the heavier mineral oils. Its well-known corrosive properties are injurious not only to human beings but also to animal health and to vegetation alike. At its conference at Harrogate in October 1964, the National Society for Clean Air presented a timely report on this subject arising from research carried out by the Technical Committee of the Society (*Sulphur Dioxide as an Atmospheric Pollutant*. Pp. 32. London: National Society for Clean Air, 1964. 2*s*.). From the outset it is frankly admitted that there is no single solution to this sulphur problem and therefore the purpose of the report is to ". . . break the problem down into its component parts, both in respect of the different sources of pollution and the possible lines of attack on each". Sulphur is present in certain fuels in both mineral and organic forms, and, since the continued use of sulphur-bearing fuels is to-day unavoidable, there is little hope of removing it before combustion. Thus the problem resolves into ways and means of efficiently dispersing the products of combustion where sulphur dioxide is potentially active, and, when it is practicable, using non-sulphur-bearing fuels and sources of heat and power that are virtually sulphur-free, such as nuclear and hydro-power, gas, and the lighter mineral oils. "For larger installations, such as power stations, the policy of discharge of flue gases from chimneys at high velocity, to secure effective dispersion, is regarded as preferable to the wet washing processes that have been tried. . . . Chimneys should be designed to be of a height that will give satisfactory dispersion of flue gases, and these needs should not be subordinated to architectural and landscaping considerations. . . . If the latter are of paramount importance . . . the building should be equipped with heat or power installations that do not require chimneys". The report also considers the importance of low-level sulphur dioxide emission from domestic chimneys, and here the picture is a somewhat brighter one, especially in smoke control areas, where modern preventive measures are aimed at eliminating smoke (hence winter fogs), incidentally reducing substantially the amount of sulphur dioxide polluting the air, or getting rid of this hazard altogether. It has been estimated that by using town gas, paraffin or light domestic oil, as, for example, in oil-fired domestic boilers, there is a 99 per cent reduction in sulphur dioxide pollution of air; with solid fuel room-heaters, up to 60 or 70 per cent reduction; with electricity low-level emission is entirely replaced by high-level emissions. In the final section of the report, "Conclusions", it is stated: ". . . the problem of sulphur dioxide in the atmosphere is one that calls for a variety of contributory solutions . . . there is no prospect in the immediate future of entirely eliminating this gas, but . . . through the means that have been indicated, much can be done to reduce its concentration in the air we breathe".

British Species of *Lepidodendron*

THE publication of *Fossil Plants of the Carboniferous Rocks of Great Britain* (Second Section), part 3, is welcome, for it has been long delayed (Memoirs of the Geological Survey of Great Britain. Palæontology, Vol. 4, part 3. Pp. 217–354. Pls. 59–81. London: H.M.S.O., 1964. 140*s*.

net). Kidston first prepared it long ago as a complete review of the British species of *Lepidodendron* and certain other genera, nearly all the specimens on which it is based being in his own collection. It was unfinished when he died and Dr. Crookall then undertook its revision and re-wrote it, but this again was not quite finished when he retired in 1952; it is now completed with the help of four other authors. The volume describes the bark types of all the British species of *Lepidodendron* and certain other genera: it deals with this aspect only. The treatment is full and careful, as one expects in a survey memoir, the synonymies are critical and often very long, and the photographs are beautiful, nearly all being at natural size or at low magnifications. The treatment is conservative; the criteria used to distinguish species are well-tried and long-accepted ones and very few new species are made. It is rather striking, however, to find how many of the species are rare and little known in Britain, though perhaps commoner elsewhere. After looking at the figures one should be able to identify a *Lepidodendron* reliably, and this should be useful. Most of the commoner kinds do indeed have rather long time-ranges, but these ranges extend over a fraction only of the Carboniferous, so that when a number of determinations are taken together it should be possible to correlate a horizon fairly well.

Imperial College of Science and Technology

The *Prospectus 1965–66* of the Imperial College of Science and Technology contains the customary information on senior academic staff, and on courses offered at the Royal College of Science, the Royal School of Mines, and the City and Guilds College, scholarships and postgraduate awards, etc. (Pp. viii+74+5 photographs. London: Imperial College of Science and Technology, 1964). Fuller information, including a short history of the College and a list of student awards, is contained in the *Calendar 1964–65*. A booklet has also been issued giving information on shorter postgraduate courses to be held at the College in the autumn term of session 1965–66, with advance information on those to be held in the spring and summer terms where known (Pp. 16. London: Imperial College of Science and Technology, 1964). Information is given separately on part-time and short full-time courses.

University College, London

The *Calendar 1964–65* of University College, London, includes a short history of the College and the usual particulars of officers, governors, committees and academic staff, together with prospectuses for the faculties of arts and science, law, engineering, medical sciences, the Bartlett School of Architecture; the Department of Town Planning, the Slade School of Fine Arts, and the School of Librarianship and Archives. Particulars of scholarships, exhibitions, etc., and lists of Honorary Fellows and Fellows, are also included (Pp. lxxxvii+470. London: University College, 1964).

Chelsea College of Science and Technology

The *Prospectus 1965–66* of the Chelsea College of Science and Technology contains particulars of the governing body, academic staff, and the courses leading to the new degrees of B.Sc. and B.Pharm. (Pp. 40+4 plates. London: Chelsea College of Science and Technology, 1964). The draft charter of incorporation of the new university will have been printed by the time the courses begin, in October, 1965. The policy of the College is to move to a site outside metropolitan London, to allow for expansion to some 3,000 students within a few years, and the title of the university will depend on this siting.

The Night Sky in January

New moon occurs on Jan. 2d 21h 07m U.T. and full moon occurs on Jan. 17d 13h 38m. The following conjunctions with the Moon occur: Jan. 6d 22h, Saturn 4° N.; Jan. 12d 17h, Jupiter 2° N.; Jan. 21d 15m, Mars 2° S. Mercury is 1°·2 N. of Venus on Jan. 7d 7h. Conditions are unfavourable for the observation of Mercury and Venus, both rising 2 h before the Sun at the beginning of the month and less than 1 h before the Sun at the end of the month. Mars rises at 22h 30m, 21h 50m and 20h 50m on Jan. 1, 15 and 30, respectively; its stellar magnitude is +0·2; its distance from the Earth is 89 million miles on Jan. 15 and is in Virgo. Jupiter sets at 3h 40m, 2h 40m and 1h 50 m at the beginning, middle and end of the month, respectively; its stellar magnitude is −2·2; its distance from the Earth on Jan. 15 is 425 million miles and is in Aries. Saturn sets at 20h 30m, 19h 40m and 18h 50m at the beginning, middle and end of the month, respectively; its stellar magnitude is +1·1; its distance from the Earth on Jan. 15 is 977 million miles and is in Aquarius (where it will be all year). Occultations by the Moon of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Jan. 11d 19h 56·1 m, 64 Cet (*D*); Jan. 11d 21h 06·4m, ξ′ Cet (*D*); Jan. 13d 19h 32·0m, 163B. Tau (*D*); Jan. 14d 19h 48·4m, ι Tau (*D*); Jan. 15d 03h 25·2m, 109 Tau (*D*); Jan. 15d 18h 04·4m, 1 Gem (*D*); Jan. 19d 23h 48·3m, 46 Leo (*R*)—(*D* refers to disappearance and *R* to reappearance). The Quadrantid meteors are active in the period Jan. 3–5. Conditions for observation are favourable but maximum occurs during daylight (Jan. 3d 12h). The Radiant is at 232° R.A., +50° Dec.

Announcements

Prof. Hans K. A. S. von Euler, one of the greatest pioneers of modern biochemistry, in particular enzymology, died peacefully in Stockholm on November 6. Prof. Euler celebrated his ninetieth birthday on February 15, 1963 (*Nature*, **197**, 436; 1963). In spite of his great age he remained active until the end.

Sir Edmund Hirst, immediate past-president of the Royal Society of Edinburgh and Forbes professor of organic chemistry in the University of Edinburgh, has been awarded the Gunning Victoria Jubilee Prize for 1960–64 of the Royal Society of Edinburgh, in recognition of his distinguished contributions to the chemistry of the carbohydrates.

A seminar on "Fatty Acids" will be held at the Regional Research Laboratory, Hyderabad, during the first week of February. Further information can be obtained from the Director, Regional Research Laboratory, Hyderabad 9.

A conference on "Electronics Design" will be held at the Institution of Electrical Engineers, London, during February 8–9. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

The second regional conference on "Electron Microscopy in Far East and Oceania", arranged under the auspices of the International Federation of Societies for Electron Microscopy, will be held in Calcutta during February 2–6. Further information can be obtained from the Electron Microscope Society of India, Saha Institute of Nuclear Physics, 92 Acharya Prafulla Chandra Road, Calcutta 9.

A symposium on "Catalysis", organized by the Bradford Chemical Society and the Department of Chemical Technology of the Bradford Institute of Technology in conjunction with the Yorkshire Council for Further Education, will be held at the Bradford Institute of Technology on February 6. Further information can be obtained from Mr. W. A. Straw, Department of Chemical Technology, Bradford Institute of Technology, Bradford 7.

PRIVATE FOUNDATIONS IN THE UNITED STATES

INFORMATION on research and other activities of 272 private philanthropic foundations gleaned from a survey conducted by the U.S. National Science Foundation in 1960 is summarized in a report issued by the Foundation *.

Research funds accounted for 20 per cent of the total expenditure of 437 million dollars for all activities of these foundations, and of the remainder 72 million dollars represented funds for medical research or research related to health and education, of which 47 million dollars was for research and 25 million dollars for education. Eighty-nine million dollars of the total research expenditure came from 177 of these foundations and of this 85 per cent was for current operating expenses and 14 per cent for new capital expenditure. Seventy-six million dollars went to research carried out by the foundations' personnel in the United States and abroad, and almost 15 million dollars was spent on intramural research. All but 12·5 million dollars of the extramural expenditure was spent within the United States, and of the 62 million dollars so spent 35 million went to colleges and universities, 11 million dollars to hospitals and 8 million dollars to independent non-profit research institutes.

More than half the 76 million dollars spent on research by the 177 private foundations went on basic research projects, the total in 1960 reaching 42 million dollars, of which 8 million dollars represented funds for basic research by individuals and 34 million dollars for projects conducted in outside organizations. Of the total, 22 millions were spent on the life sciences, 10 millions on the social sciences, 6 millions on the physical sciences, and 2 million dollars on psychology. Three-quarters of basic research funds for the life and physical sciences were used extramurally. The financial support of applied research by private foundations totalled 34 million dollars, and four-fifths of this was allocated to the social and life sciences.

In January 1961, 59 of the 272 foundations replying reported employment of 758 scientists and engineers, and of this number 650 were working full-time including 441 scientists and engineers engaged on research.

The four foundations with the largest research programmes accounted for 52 per cent of the total research expenditure. Out of the 177 private foundations twelve spent more than 1 million dollars on research in 1963. These accounted for 63 million dollars of the total. Intramural research amounted to almost 10 million dollars and extramural research to 53 million dollars, or 71 per cent of the total funds spent by all the foundations surveyed.

Research grants going to educational institutions from the twelve foundations spending more than 1 million dollars amounted to 24 million dollars, or more than two-thirds of the total of research funds from this source, while 28 million dollars (three-quarters of the total) went to hospitals, and 4 million dollars to independent non-profit research institutions.

WOOL SCOURING

THE large international attendance at a colloquium on "Wool Scouring", held at the Commonwealth Scientific and Industrial Research Organization Division of Textile Industry, Geelong, Australia, on October 26, was indicative of the growing scientific interest in this traditional process. Participants included representatives from industry, universities and technical colleges, research organizations, the Australian Wool Board, and the International Wool Secretariat.

In his opening paper on "The Importance of Scouring", Dr. M. Lipson, chief of the Division, gave a broad survey of the requirements of good scouring. From a consideration of the contaminants present on the fleece, he went on to discuss the various methods of removing them, and some of the effects of these methods on the subsequent behaviour of the wool in processing. He deprecated the still-common attitude of merchants who demand a conventional appearance rather than a good processing performance from the wool they buy, but forecast that this would disappear as the industry took more account of scientific advances in processing.

Mr. W. W. Mansfield's talk on "The Fundamentals of the Detergent Process" covered the behaviour of surface-active materials in solution, adsorption at interfaces, the removal of solid and liquid contaminants from surfaces, and the behaviour of charged particles in an emulsion. He emphasized the importance of a kinetic approach to detergency problems, particularly in industrial problems where conditions are far removed from the ideal conditions of classical surface chemistry.

Recent research on scouring at C.S.I.R.O. was described by Dr. G. F. Wood. The first part of his talk covered the development of the detergent-jet scouring process, and presented the results of investigations into the effects of various factors on scouring efficiency. In the second part, he described anomalies in the behaviour of certain non-ionic detergent solutions when used for scouring wool by the jet method. Differences in the ease of removal of oxidized and unoxidized wool wax from the fibre did not explain the anomalies, and it was suggested that they might be due to surface phenomena at the air/liquid interface of the jets.

In the final paper of the morning session, Prof. M. Chaikin made a statement on the present-day position of the "Compression Jet Scouring" process, which has developed from work carried out at the University of New South Wales.

Mr. P. H. A. Strasser outlined the history of synthetic detergents in relation to the textile industry and described the manufacture of non-ionic detergents. He discussed the changes that are taking place in the detergent industry, and showed how the demand for biodegradability was affecting the raw materials used for both anionic and non-ionic detergents.

There followed a critical appraisal by Mr. L. E. Way of the present situation in the scouring industry. He discussed quality requirements and cost limitations in relation to possible improvements resulting from chemical and mechanical modifications, and pointed out that quality control was hampered in some cases by lack of suitable measuring and control instruments.

The final paper, from Dr. C. A. Anderson, reviewed the present position in recovery of wool grease and effluent disposal. Dr. Anderson described the structure of wool scour liquors, and showed how various factors affected the centrifugal recovery of wool grease. He presented estimates of the capital and operating costs of the available effluent treatment processes, and concluded that solvent

scouring (which does not produce a noxious effluent) is the most attractive to mills where this scouring method is acceptable.

The sessions were admirably chaired by Dr. E. G. Carter and Dr. G. Laxer of the International Wool Secretariat, Mr. W. A. May of the Australian Wool Scourers' Association and Dr. F. G. Lennox of the C.S.I.R.O. Division of Protein Chemistry. The papers were followed by lively discussion, which contributed considerably to the success of the colloquium.

The lectures will be published in full in the next few issues of the *Textile Journal of Australia*.

HIGH-TEMPERATURE DYEING

A HALF-DAY conference on "Continuous High-temperature Dyeing" was held at the Shirley Institute, Didsbury, Manchester, on November 18. The conference consisted of two lectures given by staff from the Institute, each followed by an interval for discussion. In a joint paper, entitled "The Principles and Scope of Continuous High-temperature Dyeing", Mrs. B. J. Bonwitt and Mr. M. G. Corless dealt with the technical requirements of the process and the range of fibres and dyestuffs to which the technique is applicable. The differences between American and European practice were described. Whereas in America processing speeds are usually of the order of at least 100 yd./min, in Europe it is uncommon for speeds to exceed 30 yd./min. The difference in approach can be ascribed to the difference between the structures of the two industries. Rather surprisingly it appears that machinery designed to run at lower speeds has to be somewhat more refined than that designed for high-speed operation.

In the second paper, entitled "Modern Continuous Dyeing Machinery", Mr. L. J. Gibson reviewed the machinery at present available from Continental machinery makers and then went on to discuss economic factors. 'Thermosol' and pressure steam ranges are not economical for short runs. In general 4,000–5,000 yd. must be regarded as the minimum length at one shade; runs in the United States are commonly of the order of 20,000 yd., and 10,000 yd. is regarded as a minimum.

'Thermosol' machinery is being used primarily for the dyeing of polyester/cotton blends; padding systems are not yet sufficiently well developed to deal with the majority of continuous filament synthetic fabrics. Pressure steam ranges are only just coming into use and are primarily used for continuous filament viscose rayon fabrics. However, they show considerable promise for the dyeing of woven nylon fabrics. It seems certain that a major reorganization of the merchanting system will have to take place before continuous high-temperature dyeing can be exploited to the full, despite its many technical attractions.

The questions which followed both lectures led to discussions on continuous preparation, the desirability or otherwise of heat-setting before padding, the merits of infra-red pre-drying and several other points. A measure of the interest in the subject of the conference lies in the fact that 160 people accepted invitations to attend (the conference had to be repeated on November 19, it being impossible to accommodate all on one day). In addition to members of the Shirley Institute, representatives were present from the major Continental machinery and dyestuff manufacturers.

BIOENERGETICS

A SYMPOSIUM on "Bioenergetics" was held at the University of Western Ontario, London, Canada, during October 15–16 under the auspices of the Biochemistry Division of the Chemical Institute of Canada. The papers dealt, in three successive half-day sessions, with energy transformations in the plant, microbial, and animal kingdoms. Interest in the symposium was evident from the attendance: 225 scientists were present from places as far away as Halifax, Edmonton and California.

One of the highlights of the meeting was the after-dinner speech by Dr. R. Y. Stanier (University of California) on comparative aspects of the cytological structures involved in energy transformations. Most aerobic bacteria possess no recognizable intracellular membrane components comparable with mitochondria. While it is possible to isolate fragments (presumably derived from outer cytoplasmic membranes) which contain oxidative enzymes, it is probably correct to view the whole bacterial cell as the smallest respiratory unit. The forms of photosynthetic structures present great variety in procaryotic cells. The chromatophores of the purple bacteria resemble the internal lamellæ seen in chloroplasts of higher forms. The lamellæ may appear as intrusions of the cytoplasmic membrane, as vesicular elements in the cytoplasm, or as transitions between the two forms. These primitive structural analogues of the chloroplast may be interpreted as early experiments on the path to evolution of the discrete, membrane-contained organelles of present-day higher organisms.

Mechanisms and intermediates of the phosphorylation reactions associated with photosynthesis were explored by Dr. D. I. Arnon (University of California) and Dr. A. T. Jagendorf (Johns Hopkins University). Central to these and subsequent discussions on photosynthesis was the role of ferredoxin, a low-molecular-weight protein containing stoichiometric proportions of non-hæm iron and sulphide, and possessing a redox potential at physiological *p*H in the neighbourhood of that for the hydrogen electrode. One of the more interesting functions of this strongly reducing electron carrier is its ability to promote net synthesis of pyruvic acid from acetyl coenzyme A and CO_2, a reaction of especial significance to *Chromatium* where the primary products of photosynthesis are amino acids. The photoreduction of ferredoxin by activated chlorophyll appears to be a primary reaction in photosynthesis leading to generation of high-energy phosphate compounds, the production of reduced pyridine nucleotides for CO_2-fixation, and the evolution of molecular oxygen. By alternating light and dark periods of exposure of isolated chloroplasts it is possible to demonstrate formation in the light of a high-energy compound with a short half-life which is capable of later transferring its energy equivalents to ATP in the dark. The nature of the intermediate is not established as yet, but its formation is associated with structural changes in the chloroplast and the uptake of hydrogen ions. Dr. Jagendorf provided some illuminating speculations concerning the relationship of these events to the known contractile changes of mitochondria and the anisotropic membrane ATPase theory of Mitchell.

The primary event of photosynthesis, the quantum-trapping, charge-separating mechanism which leads ultimately to the splitting of water into molecular oxygen and reducing equivalents of hydrogen, was described by Dr. N. E. Good (Michigan State University) and Dr. B. Kok (Research Institute for Advanced Studies, Baltimore). The process appears to involve an aggregate of

chlorophyll molecules, which acts as a light-gathering structure analogous to a lens, transferring and focusing the energy from a single photon to a photochemically active electron sink. Kinetic studies, based on combinations of selective inhibitors of oxygen evolution with the photochemically active site, have shown that the aggregate unit possesses approximately 2,500 chlorophyll molecules for each active oxygen-producing site. Losses in the energy transfers are compensated by an extension of half-life of the activated pigment molecules; an additional factor extending the stability of the excited pigments involves reaction with an associated electron carrier (probably cytochrome *f*) in a charge transfer complex. The entire process of photosynthesis may be viewed as an extension of the life-time of energy storage forms, from the activated singlet state of chlorophyll (half-life about 10^{-8} sec) to reduced pyridine nucleotide (half-life about 1 sec).

The problem of energy-production in certain autotrophic bacteria was broached by Dr. W. W. Umbreit (Rutgers University) and Dr. H. Lees (University of Manitoba). The inability of obligate autotrophs such as *Thiobacillus thio-oxidans* to grow with carbon sources other than carbon dioxide is unexplained since the organism possesses a full complement of enzymes for glucose metabolism, and converts ^{14}C-glucose into cellular protein. *Thiobacillus* can be adapted to survive in the absence of carbon dioxide in a glucose medium under certain conditions but does not remain viable. The reduction of pyridine nucleotide for fixation of carbon dioxide by *Nitrobacter* does not appear to proceed by a direct pathway, since the redox potential for the oxidation of nitrite to nitrate is too high to permit a direct coupling of the two reactions. The initial electron transfer is to cytochrome *c*; reduction of pyridine nucleotide occurs by an energy-requiring reversed electron flow from cytochrome *c*, a reaction demonstrated previously in mammalian mitochondria and also reported for *Escherichia coli*.

Studies of oxidative phosphorylation in *Mycobacterium phlei* were described by Dr. A. F. Brodie (University of Southern California). The oxidation of malic acid by cytochrome-containing particles from this organism proceeds via two different enzyme reactions. The first is the typical pyridine nucleotide-linked dehydrogenase; the second path proceeds by a flavin-mediated reduction of a naphthoquinone. Depletion of particulate naphthoquinone by irradiation with long-wave ultra-violet light causes inactivation of oxidation and phosphorylation with a variety of substrates. Restoration of activity on addition of synthetic and natural quinones revealed two sites of interaction with the electron transport system for pyridine nucleotide-linked substrates, and an additional site for succinate. The session on bacterial energetics was fittingly concluded by Dr. R. M. Hochster (Department of Agriculture, Ottawa) with a discussion of some unsolved problems in this area. Major difficulties in assessing the efficiency of oxidative phosphorylation in microbial systems arise from the presence of high phosphatase activity and the existence of by-passes in the oxidative reactions.

The dynamics of carbohydrate metabolism in mammalian cells was discussed by Dr. G. R. Williams (University of Toronto) and Dr. E. Shrago (University of Wisconsin). by continuous monitoring of $^{14}CO_2$ released from carboxyl-labelled substrates by respiring liver mitochondria *in vitro*, it was possible to calculate the rate constants for utilization of intermediates of the tricarboxylic acid cycle. The rate constant for fumaric acid was considerably greater than that for succinic acid, suggesting that succinic dehydrogenase is a limiting component of the cycle. On the *in vivo* level, studies of enzymes in animals rendered diabetic by alloxan treatment revealed marked alterations in pathways of carbohydrate metabolism. The most dramatic change was the marked increase in activity of the soluble enzyme, phosphoenolpyruvic acid carboxykinase, in liver; since the increase was reversed by injection of insulin it would appear that this enzyme plays a major part in the endocrine regulation of gluconeogenesis.

Dissection of the mitochondrial oxidative phosphorylation process into its partial reactions was presented by Dr. C. L. Wadkins (Johns Hopkins University). A protein of low molecular weight which catalyses an exchange reaction between adenosine diphosphate and adenosine triphosphate may be extracted from liver mitochondria; simultaneously, the phosphorylation coupled to cytochrome *c* oxidation is abolished, and may be restored by addition of the purified exchange enzyme to the depleted mitochondria. The exchange enzyme appears to correspond in its action and properties to the coupling factor III described by Green *et al.* Kinetic studies indicate that ferro-cytochrome *c* combines at two sites on the exchange enzyme; interaction at one site is blocked by dinitrophenol, while azide or oligomycin *A* prevents combinations at both sites.

Dr. W. Chefurka (Agricultural Research Institute, London) presented comparative data on the lability of phosphorylation reactions in mammalian mitochondria and insect sarcosomes. The rapid ageing of insect mitochondria is related to the rapid release of free fatty acids from mitochondrial lipids. The most sensitive indicator of the ageing process is the adenosine triphosphate cleavage occurring in the presence of dinitrophenol. The disappearance of the latter enzyme on ageing may be reproduced by *in vitro* addition of fatty acid.

The symposium was well organized by a local committee under the chairmanship of Dr. K. P. Strickland. Fortunately, sufficient time was allowed for free discussion of the stimulating data and ideas presented in the formal papers. All present at the symposium were able to participate in several interesting functions concerned with nutrition, digestion, and the products of fermentation. Plans are under way to publish the papers in the *Canadian Journal of Biochemistry*.

W. C. McMURRAY

OCEANOGRAPHY IN BRAZIL

THE recent symposium on the oceanography of the western South Atlantic organized by the Brazilian Academy of Sciences (Rio de Janeiro, September 14–18) was an important step in the development of the investigation of the sea in South America. For many years there has been an active interest in oceanography in Brazil. Initially this manifested itself in the establishment of the Instituto Oceanografico in the University of São Paulo and the acquisition of field stations, one at Ubatuba situated close to an inviting range of sub-tropical marine environments, and the other at Cananéia amidst an extensive mangrove swamp with its exciting scientific problems. These facilities encouraged an energetic interest in marine biology.

The Brazilian contribution to the symposium strongly reflected this initial interest but also showed how widely the field of work has since developed. Other laboratories have entered the field, and the papers presented included investigations of the Brazil current, of water movements nearer to the coast, the drift of littoral sediments, the production of organic matter, the biology of the plankton and benthos, and geophysical investigations of the sea-bed.

Delegates from Argentina and other South American countries contributed accounts of similar investigations extending southwards to the waters of the Antarctic, and it was clear that an important aspect of a meeting such as this lay in bringing together for the first time

scientists who often have to work in comparative isolation at widely separate places. A number of invited papers from abroad on the oceanography of adjacent regions or on more general problems of oceanography formed a background for the symposium.

The amount of resources devoted to marine science in Brazil is still not great, but as a visitor one could not help being deeply impressed by what has been achieved on slender resources and particularly by the great enthusiasm displayed by the younger scientists. In all fields the awareness of the need for aiming at quality rather than quantity of work stood out very clearly. There is a growing appreciation of the importance of oceanography to the country. The need to learn more about available fisheries and to deal with the problems of defence of a very long coastline has stimulated interest in the Government and in particular in the Navy. Indeed, the Hydrographic Office has with the help of Unesco already almost completed the reconstruction of a research vessel, *Almirante Saldanha*, which will rank among the largest in the world. She will have an enormous potential for making much needed observations in the Brazil current, but it is to be hoped that such splendid facilities for making observations will not submerge the promising laboratory work which is also gaining impetus. Descriptive oceanography in all disciplines must be paralleled with adequate theoretical and experimental work before we can expect to reach a real understanding of what happens in the sea. Brazil has the potential to undertake these investigations, and it is hoped that adequate support will be found for them.

Ronald I. Currie

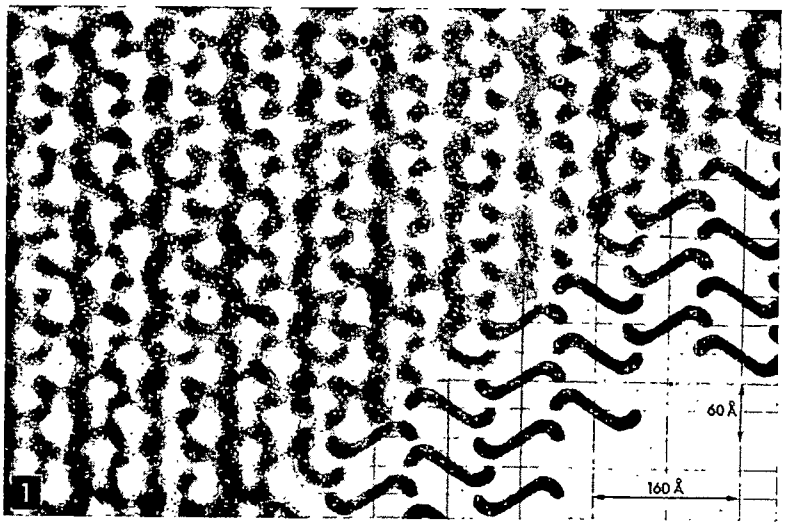
APPLICATIONS OF MICROFILM READERS IN PETROGRAPHY

MICROFILM recording of original documents is established practice, so also is the use of microfilm readers in their enlargement. In the more specialized field of petrographic investigations of igneous, metamorphic and sedimentary rocks, the use of microfilm readers in direct analysis of these materials may not be so generally known. In an article by Radco Kühnel, of the Institute for Mineralogy, Petrography and Geochemistry, Mining Academy, Ostrava, U.S.S.R. (English translation), entitled "Microfilm Reader in Petrography" (*Jena Review*, No. 3, 1964; VEB Carl Zeiss Jena, Jena (Saale)), the potentialities of this adaptation of a modern technique are both lucidly explained and convincingly illustrated.

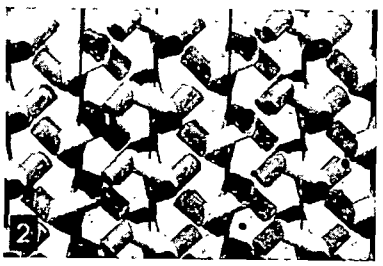
Taking the ordinary thin section of a rock of conventional thickness about 30μ, as normally examined under a petrological microscope, and assuming that the average size of the slide fits comfortably within a 35-mm microfilm frame (which according to European custom it should do), then the simple process of placing the thin section under the microfilm reader results in a magnified natural image of the section, coloured if appropriate minerals are present, giving not only a clue to identification of at least some of the more easily recognized constituents, but equally to the microstructure and texture of both rock and minerals scrutinized. One initial advantage of this approach to a petrographic investigation is that the whole rock-slice, within the reader frame, can be seen as one field and in complete continuity, avoiding any interruption in analytical assessment of mineral composition and microstructure sometimes occasioned by constantly changing horizontal and vertical orientations of these features in the normal course of microscopical examination. There is of course nothing new in projection of part or, if the original image is small enough, the whole of a thin section of rock or particles by a petrological microscope and suitable optical bench and illumination, on to an appropriate wall-screen, especially for class-instructional or other demonstration purposes; but the microfilm reader, properly adapted, simplifies this operation.

Among advantages claimed by the author for microfilm reader technique, he mentions the following: ". . . measurements may be carried out on mm-graph paper, etc. . . . for determining the absolute size of the individual grains . . . the grain-bonding figure (average number of adjoining grains)". "As regards the texture, it is a simple matter to ascertain the regularity of the spatial distribution as well as the orientation of the individual minerals. . . . In certain rocks (especially those rich in melanocratic constituents) it is possible to carry out modal determinations by means of a self-produced lattice. . . . Especially in sediment petrography it has given invaluable service in the investigation of the fine stratification, in post-sedimentary deformations, rhythmic precipitations, of gradation symptoms and other lithological phenomena." It is also possible to use this apparatus to explore thin sections of rocks in polarized light and with crossed nicols on the available projection area of the instrument, and with a more powerful light-source if it is desired to project the image on to a wall-screen for instructional purposes. Another application of the microfilm reader is in photographic documentation of rock micro-structure and micro-texture. In this connexion the author briefly describes his work on 'negative micro-exposures', that is, on direct exposure of the section to photographic paper; he also indicates the possibility of producing direct micro-colour photographs of rocks and minerals by means of coloured reversal paper.

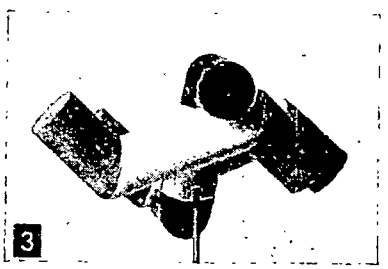
VEB Carl Zeiss Jena (C. Z. Scientific Instruments, Ltd., London, W.1) manufacture what they call a 'Dokumator Film Reader' which appears to be ideal for the purposes described here. In this apparatus the image appears on a 300 mm × 390 mm screen of high reflective power. An attachment for slides permits viewing of glass slides up to 50 mm × 50 mm in area, but it is to be noted that some special arrangements would have to be made if conventional British 75 mm × 25 mm glass slides are involved; alternatively, the smaller foreign-type mounts might have to be used.



H. B. Milner



SUB-UNITS OF THE CATALASE MOLECULE SEEN BY ELECTRON MICROSCOPY



By Dr. R. C. VALENTINE

National Institute for Medical Research, Mill Hill, London, N.W.7

CLEAR pictures of protein molecules are difficult to obtain with the electron microscope, although in size the molecules should be easily within its resolving power. At present, negative staining is the most generally successful way of showing detail down to the molecular level. This is done by drying some dense but unreactive substance with the specimen; the relatively electron-transparent objects are outlined by the far more opaque 'negative stain'. When applied to protein molecules, this technique works less well with some proteins than with

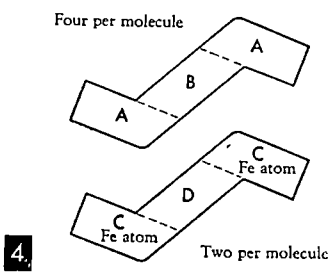


Fig. 1. Part of an electron microscope picture of a catalase crystal at a magnification of 1,250,000 times. The sub-units seen in the plane of the picture are indicated at the lower right. Fig. 2. A model of the suggested arrangement of the crystal showing how two perpendicular sets of similar sub-units can give a pattern resembling that of Fig. 1. Fig. 3. A model of the proposed half-molecule of catalase containing three sub-units each of 42,000 molecular weight. The sub-unit with the darker ends, though similar to the other two, is not identical with them. Fig. 4. A diagram showing one way of reconciling the electron microscope appearance with the chemical data. The whole molecule might be built from 18 polypeptide chains of four kinds *A*, *B*, *C*, and *D*. Each chain contains 120 amino-acid residues and has a molecular weight of 14,000. The *C* chains are the only ones to contain a hæm group. In the half molecule (Fig. 3), two sub-units containing chains *A* and *B* are linked by one (shown with darker ends) containing *C* and *D*. Thus the whole molecule of six sub-units has 8 *A*-chains, 4 *B*-chains, 4 *C*-chains, and 2 *D*-chains. One iron atom in each *C*-chain (or alternatively one in each *B*-chain) then gives 4 iron atoms per molecule

others. The difference is not related to molecular size, and the explanation, though very likely concerned with penetration of the stain into the molecules, is not clear. However, in some cases the pictures seemed good enough to suggest the general shape of the molecules[1]. The conclusion was that the electron microscope did not support the cigar-shape which had been the widely accepted picture derived mainly from ultracentrifuge data. As a first approximation, non-fibrous proteins appear to have spherical molecules; axial ratios greater than two were not seen.

The chances of obtaining detailed electron microscope pictures of protein molecules are very much improved when it is possible to examine the proteins in crystalline form. The advantage of crystals as specimens was first pointed out by McLachlan[2], who suggested a scheme that might allow the electron microscope to 'see atoms'. The regularly arranged molecules in the crystal would not be very clear on the original electron micrograph. But the suggestion was made that it should be possible when enlarging the negative to superimpose tens or hundreds of different molecules. This is done by making multiple exposures in the enlarger with the image shifted between each exposure by exactly the repeat distance. Such a synthesized picture should show much more detail than was clear in the original, and indeed a successful application of this sort of idea to tobacco mosaic virus has recently been described[3]. An additional advantage of crystalline material is that there is less denaturation of the molecules during preparation of the specimen. The only difficulty is to obtain thin enough crystals.

Catalase is an enzyme which forms thin micro-crystals very suitable for electron microscopy. Crystalline bovine-liver catalase (C. F. Boehringer und Soehne, Mannheim, Germany) was therefore examined after treatment with a high-contrast negative stain (sodium silicotungstate or uranyl acetate). A Philips *EM* 200 electron microscope was used which had been adjusted to give a resolution measured on Fresnel fringes of at least 5 Å.

The molecular weight of catalase is 250,000, and in agreement with this, as already reported, the microscope shows the free molecules around the crystals as roughly spherical, or perhaps cubical, objects 70–80 Å in diameter. But molecular detail could not be clearly distinguished from background grain. The crystals themselves showed a remarkable variety of repeating patterns which were

seen to change when the specimen was tilted in the microscope. From the contrast of the unstained crystals, it was estimated that many of them were 200–500 Å thick; they would therefore contain several layers of molecules. The variation in pattern with orientation is thus understandable, though it adds to the complication of interpreting the pictures. However, it did become clear after an examination of many high-resolution electron micrographs that it would be difficult to maintain the initial idea[1] that the crystal was a simple array of the 70-Å molecules. Lucy and Glauert[4] have therefore suggested that the crystal is composed of an array of sub-units of the molecule and have devised a model on this basis which gives a much better explanation of the pictures.

More than twenty-five years ago Sumner and Gralén[5] showed that catalase could be split into smaller molecules in acid or alkali. Recent work with the ultra-centrifuge[6–10] and chemical investigations[11,12] now clearly show that the molecule of 250,000 molecular weight is composed of sub-units. How many, however, is a matter of some dispute. An approximate treatment of the ultra-centrifuge data suggested that the molecule could be split into four identical sub-units[9]; this conclusion was based on the assumption that the sub-units had nearly the same shape as the molecule. Other workers, after much fuller investigations, have come to the conclusion that there must be six similar sub-units[8,10]. The only difficulty in accepting this is that catalase contains four atoms of iron per molecule. Thus, if it is built of identical sub-units, one would strongly suspect *a priori* that there should be two or four but not six of them. The chemical estimations of the number of sub-units have changed the other way. Initially the workers favoured six sub-units[11], and after further work[12] found it "not unreasonable to incline towards four". What does seem to be established[10] is that at *p*H 3 catalase molecules can split into identical half-molecules. These are enzymatically unreactive but can be recombined, and up to half the enzyme activity is then restored.

In the light of this evidence the electron micrographs of the crystals of catalase were reconsidered and an attempt was made to interpret them assuming that the molecule contains either four sub-units of molecular weight 62,500 or six of molecular weight 42,000. The possibility was also considered that the crystal, like that of hæmoglobin, might be an array of the half-molecules. In examining the pictures it was found, as McLachlan had predicted, that superimposition in the enlarger of ten or twenty images from the same negative shifted by the repeat distance considerably improved the clarity of the relevant detail. Unfortunately imperfections in the crystals occur when they are dried and limit the number of repeats that can be usefully superimposed. Detail below about 15 Å is still not seen.

In what is taken as the key pattern, a sub-unit can be made out shaped something like an integral sign (Fig. 1). The width of the unit is between 20 and 25 Å and, straightened out, its length would be 120 Å. The density of catalase is 1·3 g cm^{-3} (or more strictly the partial specific volume is 0·75 (ref. 5)), and with the assumption of an approximately circular cross-section the molecular weight of the unit comes out as between 30,000 and 45,000; it is almost inconceivable that it could be as high as 60,000. The sub-unit is thus almost certainly one-sixth of the molecule and will have a molecular weight of 42,000. Fig. 1 shows the units in neighbouring rows alternately packed and the repeat distance is 160 Å (twice the distance between the rows). The repeat distance up the rows is 60 Å but between the units are clear elliptical spots about 40 Å by 20 Å. If, as the centrifuge evidence suggests, all the sub-units are similar, these spots have to be interpreted as end-on views of sub-units. The complete pattern is then explained by assuming that the crystal is built by half-molecules consisting of two parallel sub-units linked by one at right angles. A model of the crystal structure suggested is shown in Fig. 2 and the appearance of the half molecules in Fig. 3.

Although it is not clear how the two halves of the molecule fit together, there are several ways that will give an approximately spherical shape. In view of the highly elongated sub-units (the axial ratio of which is about 6), the fact that the molecule does not sediment in the centrifuge as a sphere but as an ellipsoid of axial ratio 5 (ref. 10) is understandable. Some high-resolution electron microscope pictures of glutamate dehydrogenase have been published by Horne and Greville[13], and again the ultra-structure appears to be elongated. These workers have also published[14] some preliminary pictures of catalase crystals in various orientations and suggested that they contain 'structure units'.

Recent chemical evidence[12] about catalase has already been mentioned as favouring four sub-units, but it can also fit the picture of catalase just described. In fact, since unfortunately *N*-terminal amino-acids could not be detected, a clear answer about the number of sub-units or polypeptide chains was not obtained and light on this point only comes indirectly. In outline the chemical work consisted of isolating and largely characterizing the peptides in tryptic hydrolysates of bovine-liver catalase. The catalase molecule itself (molecular weight, 250,000) has about 2,150 amino-acid residues. If the molecule did not contain any identical sub-units, the peptides obtained by trypsin digestion of one molecule would almost certainly all be different. Then, on isolating each peptide and characterizing the amino-acids in each, a total near to 2,150 should be found. If the molecule contains identical sub-units, each peptide will be repeated by up to as many times as there are sub-units in the molecule. In fact the hydrolysate contained at least 2·5 times the amount of some peptides which would be expected from a molecule of 250,000 molecular weight. This seems to establish beyond question the presence of at least three identical sub-units in catalase. On the other hand, if there were five or more identical sub-units, there should not be more than 430 (that is 2,150/5) residues found in the peptides. Since at least 460 were found, four sub-units were favoured.

The sub-units seen in the electron microscope pictures, however, are perhaps not all identical since they pack in the crystal in two different ways. Two-thirds appear to be of one kind and one-third of another. Moreover, the sub-units look symmetrical about their centres and consist of a straight portion of lower contrast than the two similar ends. The electron microscope appearance and the chemical data can be most simply accounted for by supposing that catalase is built of 18 polypeptide chains of four different kinds, each of about 14,000 molecular weight (120 residues). This would make each chain similar in size to the single chain of ribonuclease. The hypothetical structure is illustrated diagrammatically in Fig. 4. It allows there to be six similar sub-units, four of one kind and two of another, with only 4 atoms of iron per molecule and 480 residues in the tryptic digest.

I thank Mr. N. G. Wrigley for the photographic techniques and model-building involved in this work.

GOLGI CELL INHIBITION IN THE CEREBELLAR CORTEX

By Sir JOHN ECCLES, F.R.S., R. LLINÁS and K. SASAKI

Department of Physiology, Australian National University, Canberra

THE Golgi cells or large stellate cells of the granular layer were first described by Camillo Golgi in 1886 (ref. 1). These cells are among the largest neurones in the cerebellar cortex, being second in size only to the Purkinje cells. As illustrated in Fig. 1*A*, the bodies of the Golgi cells are located in the granular layer (*G*) of the cerebellar cortex, immediately below the Purkinje cell bodies, their dendrites ramifying extensively in the molecular layer (*M*) and their axons branching profusely to form a thick plexus, which is restricted to the granular layer and which enters into contact there with a special synaptic structure called the glomerulus[2]. This glomerulus is formed by the mono-synaptic contact between the terminal sacs of the most numerous cerebellar afferent fibres, the mossy fibres, and the dense surround made by the terminals of granule cell dendrites[2-4]. Although quantitative data are not available, it can be said that the axon of a single Golgi cell may enter into contact with thousands of these glomeruli. Its commonest site of termination appears to be on the dendrites of the granule cells. There are three synaptic inputs to the Golgi cells, the main one being the parallel fibre system which contacts the dendritic spines of these cells in the molecular layer[4]. These parallel fibres are formed by the terminal bifurcations of the granule cell axons at all depths in the molecular layer[2,5-7]. Thus an afferent volley in the mossy fibres will activate granule cells and these, in turn, through the parallel fibres, the Golgi cells. The other two types of synapse are located on the bodies, and are the axon collaterals of Purkinje cells[3] and the collaterals of the climbing fibres[8,9], and are presumed to be of secondary significance. The function of the Golgi cells on the mossy fibre-granule cell synapse has been studied by microelectrode recordings at various depths in the cerebellar cortex (laminar field analysis) and also by intra- and extracellular unit recordings.

The experimental procedure was similar to the one reported in previous publications[10,11]. Cats were anæsthetized with 'Nembutal' and artificially ventilated after being paralysed with 'Flaxedil'; a bilateral pneumothorax was performed in order to minimize the movements of the rib cage. Microelectrodes filled with 3 M potassium chloride or 2 M potassium citrate with an average resistance of 10 MΩ were used for intra-cellular recording. Laminar field analysis and extra-cellular unit recordings were carried out with microelectrodes filled with 4 M sodium chloride solution. The part studied was the vermal region of the cerebellum in the folia immediately anterior (culmen) or immediately posterior (lobus simplex) to the fissura prima. The cortex was covered with an agar gel which served to suppress the pulsation movements and to insulate the cortex from environmental influences, such as cooling and evaporation. Stimulation of the surface of the cerebellum (local and transfolial) and of the underlying white matter (juxta-fastigial) was done through concentric bipolar electrodes. Similar electrodes were used to stimulate the inferior olive and the external cuneate nucleus. The superficial and deep radial nerves were stimulated with platinum electrodes under paraffin oil.

When a microelectrode is lowered into the granular layer, and a large population of granule cells is simultaneously excited, a typical negative field potential is recorded. This negative field, which represents for the most part summated spikes of these cells, can be evoked by any form of stimulation capable of activating mossy fibres. For example, in Fig. 1*B* stimulation of an adjacent folium has been used to excite granule cells by a type of axon reflex along the mossy fibres, which branch profusely in the granular layer and extend in a U-shaped fashion from one folium to the next[2].

In the upper trace of Fig. 1*B* a progressive increase of such a transfolial (*T.F.*) stimulation evoked a corresponding increase in the granule cell spike potentials. In the lower trace it can be seen that a conditioning stimulation of the parallel fibres (*LOC*) removed this spike component and left only a slow negative potential wave, which is presumably the excitatory post-synaptic potential (EPSP) evoked by the mossy fibre synapses on the granule cells. In Fig. 1*C* a larger granule cell spike potential was produced by a graded juxta-fastigial (*J.F.*) stimulation. Lower traces show that the conditioning parallel fibre stimulation also depressed this granule cell spike, though it was less effective against the more powerful synaptic action produced by the *J.F.* stimulation.

In both Fig. 1*B* and *C* it will be noted that there is a pre-synaptic spike, which is small in Fig. 1*B* and larger in Fig. 1*C*. In Fig. 1*B* this spike would be produced mainly by impulses in mossy fibres, but in Fig. 1*C* the impulses in Purkinje axons and climbing fibres would make a large contribution. This inhibition of the granule cell spike potentials reached its maximum at about 20 msec from the preceding stimulus to the parallel fibres, and passed off at intervals beyond 100 msec.

The inhibition of granule cells can also be shown when action potentials from single granule cells are recorded with a microelectrode in the granular layer. In Fig. 1*D* a single volley from the superficial radial nerve evoked a repetitive discharge in a granule cell. This discharge was inhibited by a preceding stimulation of the parallel fibres (*L*). The inhibition of the repetitive spikes is complete up to 50 msec and is still present at 120 msec. This inhibitory action is also demonstrated in Fig. 1*E*, where the spontaneous discharge of several granule cells was completely inhibited for as long as 110 msec by applying a stimulus to the parallel fibres (*L*) or the underlying white matter (*J.F.*), whereas a stimulus to the inferior olive (*I.O.*) produced a shorter-lasting inhibition.

These results demonstrate the existence of a powerful inhibitory action exerted by the parallel fibres on their cells of origin, the granule cells. Anatomically, the only neural elements capable of such negative feed-back at cortical level are the Golgi cells, since they represent the only system linking the molecular layer with the granule cells, and the only synaptic input to the granule cells apart from the mossy fibres. Parallel fibre stimulation by the surface electrode (*LOC*) would excite Golgi cells through their dendrites in the molecular layer (Fig. 1*A*) and so produce inhibition of the granule cells. The inhibition effected by white matter stimulation (*J.F.*) is similarly explained, for this stimulus would directly excite mossy fibres, which, in turn, would activate granule cells and the corresponding parallel fibres.

This inhibitory depression contrasts with the climbing fibre activation, where a similar parallel fibre stimulation does not diminish the climbing fibre response evoked by inferior olive stimulation[11]. The difference is to be expected, since the Golgi cell action is exerted on the mossy fibre–granule cell synapse, whereas the climbing fibre, being in mono-synaptic contact with the Purkinje cell, has no synaptic relay at which inhibitory action can be exerted[2,9].

Another example of Golgi cell inhibition is shown in Fig. 2. An intra-cellular recording from a Purkinje cell

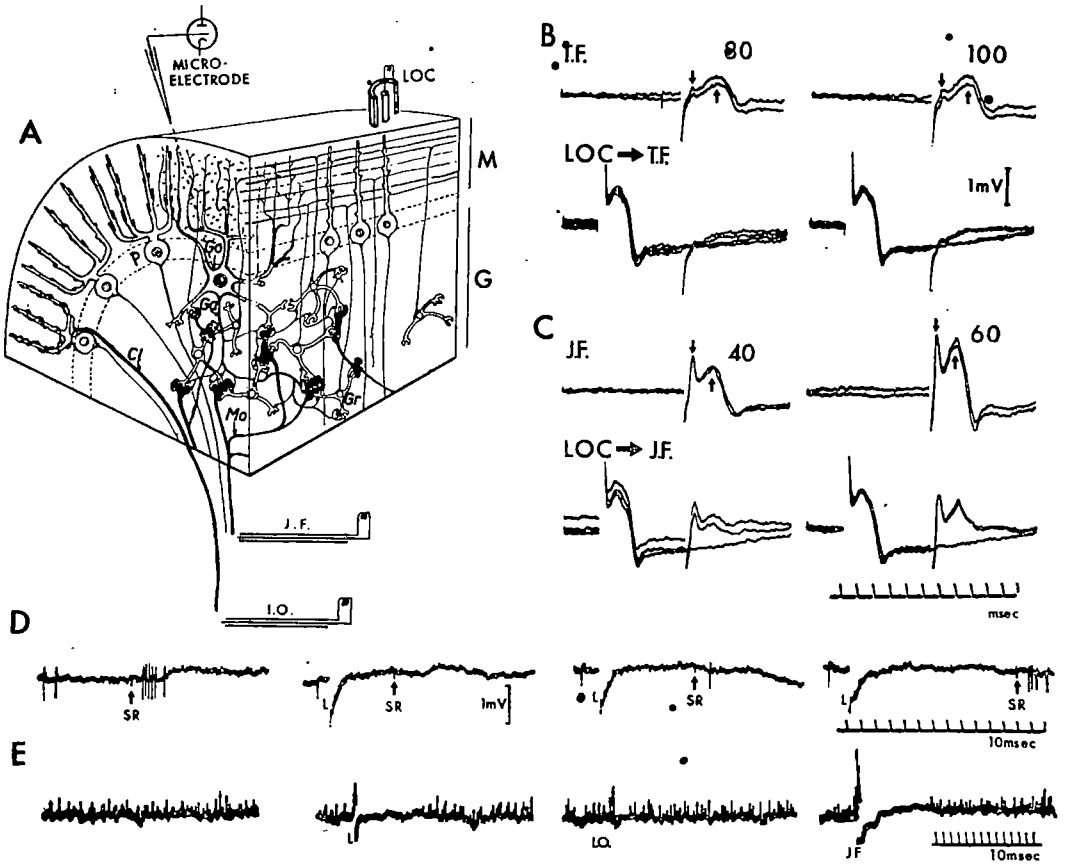

Fig. 1. *A*, Diagram of the cerebellar cortex (modified from Szentágothai, 1964 (ref. 4)) and experimental arrangementas, described in the text: *G*, granular layer; *M*, molecular layer; *Cl*, climbing fibre; *Ga*, Golgi cell axon; *Go*, Golgi cell soma; *Gr*, granule cell: *Mo*, mossy fibre; *P*, Purkinje cell soma. *B* and *C*, Potential fields recorded at 550μ depth: downward arrow, presynaptic spike; upward arrow, granular spikes. *D* and *E*, Extracellular granule cell spikes at 500μ depth

shows in Fig. 2*A* the synaptic activity evoked by a single stimulus applied to mossy fibres through the *T.F.* electrode. By means of the mossy fibre to granule pathway an EPSP is produced by the direct action of the parallel fibres on the Purkinje cells. This potential is followed by an inhibitory post-synaptic potential (IPSP) due to the inhibitory action of basket cells on axon and soma of the Purkinje cell[10,12], and by the wider inhibitory action of the stellate cells on the dendritic tree of the Purkinje cell[13]. As shown in Fig. 2*B*, both the EPSP and the IPSP of Fig. 2*A* are greatly decreased by a preceding stimulus (*L*) to the parallel fibres. On the other hand, if the testing volley is not applied to the mossy fibres, but is applied directly to the parallel fibres one synapse later (Fig. 2*C*), a preceding stimulus to the parallel fibres does not depress the synaptic potentials of the Purkinje cell (*D*). Evidently the inhibition in *B* must be occurring earlier in the pathway than the parallel fibre–Purkinje cell synapses, and hence must be effected at the mossy fibre–granule cell synapse. It should be pointed out that the large apparent increase in the EPSP evoked by the testing stimulus in *D* relative to *C* is attributable to the occlusion of its IPSP by the large IPSP produced by the conditioning stimulus.

The results presented in Figs. 1 and 2 demonstrate that there is a very effective inhibitory action on the mossy fibre–granule cell synapses, and that the excitatory action of the parallel fibres *per se* on the Purkinje cells is unimpaired by this inhibition. It is concluded that the Golgi cells have a strong inhibitory action on the granule cells and thus serve to regulate the output of the cerebellum, acting as a negative feed-back system on the dominant afferent system to the cerebellar cortex, the mossy fibres.

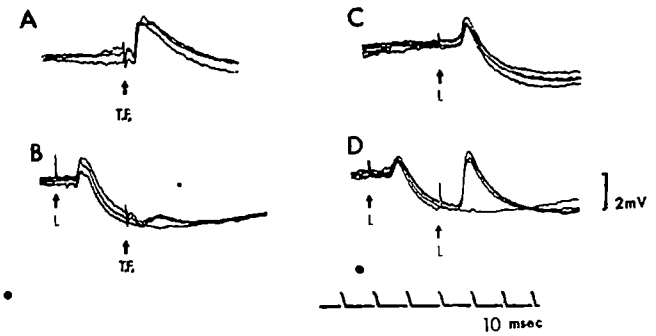

Fig. 2. Intra-cellular recording from a Purkinje cell. *A*, Excitatory and inhibitory synaptic potential evoked by mossy fibre (*T.F.*) stimulation. *B*, Depression of these synaptic potentials by a preceding parallel fibre (*L*) stimulation. *C*, Excitatory and inhibitory synaptic potentials evoked by parallel fibre stimulation. *D*, No depression by a preceding parallel fibre stimulation

RELATIVE EFFICIENCY OF HIGH-LET RADIATION (BRAGG-PEAK LITHIUM IONS) ON NORMAL RABBIT SKIN, USING INTEGRAL DOSE AS A BASIS FOR COMPARISON

By DR. G. J. D'ANGIO, PROF. J. H. LAWRENCE, DR. A. GOTTSCHALK and DR. J. LYMAN
Donner Laboratory and Lawrence Radiation Laboratory, University of California, Berkeley

THE biological effectiveness of the Bragg-peak region of a high-LET (linear energy transfer) particle relative to that of a low-LET heavy particle was examined by comparing the reactions produced in the skin of rabbit ears which had been irradiated with a beam of either lithium-7 ions (LET = 122·0 keV/μ) or hydrogen-2 ions, deuterons (LET = 17·9 keV/μ). Both beams (from the *Hilac*, Lawrence Radiation Laboratory, Berkeley, California[1]) were monitored with a parallel plate ionization chamber, previously described by Brustad *et al.*[2], with degrading foils placed after the ionization chamber to adjust the range of the particles so that they would stop within the skin and short of the cartilage of the ear. (Histological investigations showed that in animals of this size the inner skin surface averages 300μ in thickness.) The experiment was planned so that equal volume doses at the Bragg peak would be delivered within the epidermis and dermis with each of the two ions. Integral dose was used as the basis for comparison of the two qualities of radiation used in this experiment, and in this situation it is perhaps imprecise to speak of 'relative biological effectiveness' in the usual sense (see ref. 3 for further discussion of this point). Therefore, to avoid any possible confusion in terminology we shall use relative efficiency rather than relative biological effectiveness in discussing the results of these experiments.

Five groups of ten rabbits each were used (all 7·5 week-old males). Each animal had the inner surface of one ear exposed to radiation by 6·3 MeV Bragg-peak deuterons (low-LET) and of the other ear to 35 MeV Bragg-peak lithium-7 ions (high-LET). Table 1 gives the ranges and LET's of these particles at entry and within the skin of the ear. The average LET values were obtained by dividing the incident particle energy by the range. The volume dose in the skin was doubled from one group to the next, the Group V animals thus receiving 16 times the dose of Group I animals. The doses received by Group I animals are shown in Table 2. (It was noted that because of a technical error during irradiation the integral dose was slightly higher for the deuteron-irradiated ears in each group.) The deposition of energy is not uniform throughout the range of the particles: the estimated ratios of maximum dose to surface dose for lithium-7 and deuteron ion beams are 3·0 and 1·6 respectively.

In order to avoid any bias or systematic error in the investigation, involving a subjective as well as an objective evaluation of radiation response, an elaborate system for randomizing the animals in their numbering sequence and their cage assignments throughout the experiment as well as a method for weighting the assigned response scores were worked out, and these have already been described[3]. Briefly, the acute responses were graded subjectively on a 1 to 4+ scale, the observer taking into account the usual objective criteria of radiation reactions such as erythema, œdema, desquamation, keratosis, tanning and thinning. Later, 6·5 weeks after irradiation when the peak reactions for the acute response were passed, a second system was adopted for evaluating the chronic reactions. These were scored on a 1 to 6+ basis, and the criteria were various degrees of pigmentation, atrophy and telangiectasia, as well as scarring and necrosis which were considered to be accentuations of the responses.

Table 1. PHYSICAL CHARACTERISTICS OF TREATMENT BEAMS

	Ion	
	^{7}Li	^{2}H
Residual energy at entry (MeV)	35·0	6·3
Residual range at entry (μ)	287·0	352·0
LET (keV/μ)		
At entry	64·8	11·2
Within skin	122·0	17·9

'Entry' denotes the superficial skin surface. The thin skin of the rabbit ear has been assumed to be of water density for calculation purposes. To obtain the range and LET in the density-independent units mg/cm^2 and MeV/g cm^{-2} respectively, the values for the ranges given above must be divided by 10, and those for the LET must be multiplied by the same factor.

Table 2. DOSES RECEIVED BY GROUP I ANIMALS

Ion	Incident energy flux (MeV/cm^2)	Average dose (rad)	Integral dose (g rad)
^{7}Li	$1·90 \times 10^9$	1,060	86·5
^{2}H	$2·17 \times 10^9$	988	98·8

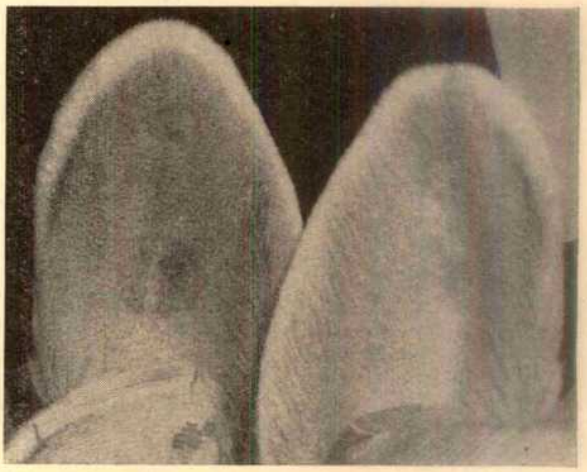

Fig. 1. Ears of Group IV rabbit three weeks after irradiation with heavy ions: right ear, lithium-7 (LET = 122·0 keV/μ); left ear, hydrogen-2 (LET = 17·9 keV/μ). Following comparable volume doses to each ear, note the pronounced reaction in the ear receiving the higher-LET radiation whereas there is only a faint response in the ear receiving the lower-LET radiation. (The unirradiated central strip on the right ear results from an unavoidable longitudinal folding of the ear during treatment)

The analysis of the acute reactions for the lithium-7 and the deuteron-irradiated ears of the five groups of animals revealed the following four patterns of response.

(1) A prompt response which increased steadily, reaching a maximum by the third to fourth week after treatment. This was observed in both ears of the Group V (highest dose) animals, although the response in the deuteron-irradiated ears consistently lagged behind that in the lithium-7 irradiated ears.

(2) A prompt response which waned and then recurred rapidly after the second week, reaching a maximum by the third week or later. This was observed in the lithium-7 irradiated ears of Groups III and IV animals.

(3) No initial reaction, but a subsequent response during the second week at the time when reactions observed in the ears of Group V animals had passed their peak and were in a subsiding phase. This was observed in

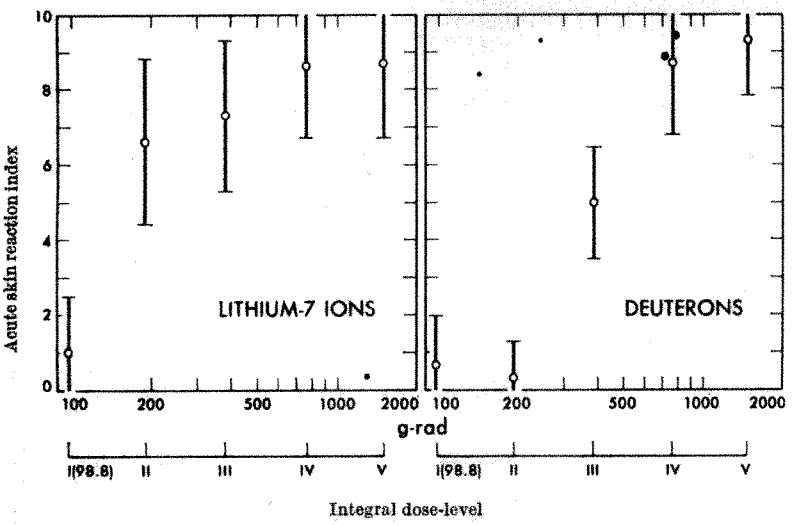

Fig. 2. Dose-response curves for lithium-7 ions and hydrogen-2 ions (deuterons). A skin reaction index of 10 represents a maximum response in all animals. Differences in reactions at dose levels II ($P < 0.001$) and III ($P < 0.02$) lead to curves of different configuration in their low-dose portions, with consequent rapid changes in relative effectiveness

deuteron-irradiated ears of Groups III and IV, and in lithium-7-irradiated ears of Group II.

(4) Minimal reactions, if any at all, which appeared 3–4 weeks after treatment. This was observed in both ears of Group I (lowest dose) animals and in deuteron-irradiated ears of Group II animals.

The acute reactions faded progressively up to the sixth week, and from then until the end of the experiment at 6 months there was little change.

Thus, these investigations of the acute reactions in rabbit ears showed that at equal times after therapy the responses were more severe in lithium-7-irradiated ears for each group (Fig. 1). The overall patterns of response before maximum reactions developed were consistent; the average reactions in lithium-7-irradiated ears at a given integral dose were equal to, or slightly greater than, those observed in deuteron-irradiated ears receiving twice that integral dose, but were not so pronounced as those in deuteron-irradiated ears receiving about four times that integral dose (that is, an efficiency of between 2 and 4). Finally, as shown in Fig. 2, the dose-response curves for the maximum acute skin reaction indices obtained (disregarding time) with each of the ion beams differed distinctly in the low-dose regions; the curve for deuterons is clearly sigmoid whereas that for lithium-7 ions had a low-threshold or no-threshold configuration. This results in a rapid change in relative efficiency as dosage is increased, the variation being from about 5 : 1 to 1 : 1 as the dosage is doubled.

The chronic reactions were also analysed. In the rabbit ears receiving single high doses of lithium-7 ions there were pronounced, but not disproportionately severe, late post-radiation changes, as compared with those irradiated in the same way with deuterons. There was no suggestion in any animal, at any time during the 6-month period of observation, of a progressive or abrupt deterioration of the chronic response towards complete necrosis or catastrophic damage.

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

RATE OF LABELLING OF MITOCHONDRIAL PHOSPHOHISTIDINE BY RADIOACTIVE INORGANIC PHOSPHATE

By Prof. E. C. SLATER and A. KEMP, jun.
Laboratory of Physiological Chemistry, University of Amsterdam

In 1961, Boyer *et al.*[1] made the important observation that when $^{32}P_i$ is added to mitochondria pre-incubated with or without substrate in the absence of added P_i or ADP, the ^{32}P is rapidly incorporated into a protein-bound phosphorus compound, later identified as protein-bound phosphohistidine[2]. Boyer[2,3] concluded that these experiments give convincing evidence that protein-bound phosphohistidine participates as an intermediate of oxidative phosphorylation. In simple terms, the course of the phosphate uptake was envisaged as:

$$P_i \longrightarrow \text{phosphohistidine} \longrightarrow \text{ATP}$$

Clearly, this theory required experimental evidence that the rate of formation of phosphohistidine from P_i is sufficient to account for the rate of synthesis of the ATP. In their first paper, Suelter *et al.*[1] showed that the maximum labelling of the mitochondrial protein-bound phosphohistidine was reached before the maximum labelling of the mitochondrial ATP, which satisfies one of the criteria for a precursor-product relationship. However, the amount of label finally appearing in the ATP was about 200 times that appearing in the phosphohistidine, and already at the time of taking the first sample (5 sec), when labelling in the phosphohistidine had reached its maximum value, 70 times more label was found in the ATP than in the phosphohistidine. Although the results were not inconsistent with Boyer's conclusion, it was clear that a more extensive investigation of the kinetics of the initial incorporation of $^{32}P_i$ into phosphohistidine and into ATP was required.

In a previous publication (Fig. 2 of ref. 4), we reported the results of such an investigation, carried out under the same conditions as in the experiments of Suelter *et al.*[1], with the exception that, in order to extend the time-scale, the mitochondria were incubated at 0°. The labelling of the phosphohistidine, measured by the procedure of Peter and Boyer[3], followed zero-order kinetics for the first 30 sec, without a measurable initial lag, and the incorporation of $^{32}P_i$ into ATP, after an initial lag lasting for about 30 sec, followed zero-order kinetics for the following 90 sec. The initial (that is, maximal) rate of labelling of phosphohistidine in the zero-order phase

was only 1·5 per cent of that of the rate of labelling of the ATP in its zero-order (also maximal) phase. Oligomycin had no effect on the initial rate of labelling of the phosphohistidine, whereas it inhibited the labelling of the ATP by 95–99 per cent. We concluded that the relatively slow rate of labelling of the phosphohistidine would seem to preclude the latter as intermediate on the main pathway of oxidative phosphorylation, and it was suggested that the phosphohistidine might be an intermediate in a slow oligomycin-insensitive pathway for the synthesis of ATP.

Pressman[5] reported evidence of a different nature which also cast doubt on the role of phosphohistidine as an intermediate of respiratory-chain phosphorylation. He found that addition of dinitrophenol, Ca^{2+} or valinomycin caused a rise in the amount of phosphohistidine and a decline in the amount of ATP.

Afterwards, Boyer[6] showed that succinyl-coenzyme *A* synthetase (*EC* 6.2.1.4) is responsible for the incorporation of $^{32}P_i$ into protein-bound phosphohistidine by extracts of liver mitochondria. A phosphorylated form of this enzyme had previously been isolated from *Escherichia coli* by Upper[7], and Boyer[6] showed that the phosphate in this enzyme is bound to a histidine residue. We have confirmed these findings using the enzyme isolated from heart muscle (Table 1).

Table 1. INCORPORATION OF ^{32}P FROM $^{32}P_i$ INTO PROTEIN-BOUND P IN SUCCINYL-COENZYME *A* SYNTHETASE

Exp.	Reaction time (sec)	Enzyme preparation (mg protein)	Addition	c.p.m. in protein-bound P
1	120	1·2	None	222
	120	2·4	None	501
	120	4·9	None	1,100
2	3	2·5	None	66
	6	2·5	None	145
	9	2·5	None	216
	13	2·5	None	335
	40	2·5	None	462
3	15	2·5	None	566
	15	2·5	Arsenite (5 mM)	566
	15	2·5	Arsenate (5 mM)	331

The succinyl-coenzyme *A* synthetase was isolated from pig heart. The reaction mixture contained 5 mM $MgCl_2$, 1 mM EDTA, 6 mM KCl, 200 mM sucrose, 100 mM *tris*-HCl buffer (*p*H 7·4), 0·09–0·12 mM succinyl-coenzyme *A*. The reaction was started by addition of $0·7 \times 10^6 - 1·3 \times 10^6$ counts/min $^{32}P_i$ (0·05–0·10 mM). Reaction volume, 1·3 ml. Reaction temperature, 0°. The amount of protein-bound P was determined by the method of Bieber *et al.*[8].

In our previous publication[4], we suggested that the slow oligomycin-insensitive pathway for the synthesis of ATP, involving phosphohistidine, might be derived from the same high-energy intermediates of oxidative phosphorylation ($A \sim C$) as in the oligomycin-sensitive pathway. However, using a highly sensitive method, we have been unable to find any measurable net oxidative phosphorylation linked with the oxidation of β-hydroxybutyrate, succinate or tetramethyl-*p*-phenylenediamine, in the presence of oligomycin. With glutamate as substrate, there was a small oligomycin-insensitive phosphorylation, which was to be expected since the substrate-linked phosphorylation step of α-ketoglutarate oxidation is not inhibited by oligomycin[9]. The addition of glutamate, but not of other substrates, was found to increase the rate of incorporation of $^{32}P_i$ into mitochondrial protein-bound phosphohistidine (measured by the new procedure described by Bieber *et al.*[8]), under the conditions of our earlier experiments.

Arsenate, in a concentration of 5 mM, strongly inhibited the incorporation into both protein-bound P and ATP, the ratio of the incorporations, after 40 sec at 0°, remaining the same (Table 2). Arsenite, on the other hand, had a much larger effect on the rate of incorporation into protein-bound P than into ATP, the ratio dropping from about 5 to about 1.

The sensitivity to arsenite and insensitivity to oligomycin suggest that the incorporation of $^{32}P_i$ into mitochondrial protein-bound P is associated with the substrate-linked phosphorylation step of α-ketoglutarate oxidation. We should now wish to modify the summary scheme shown in our previous paper[4] in the sense that the $A \sim C$ compound involved in the labelling of phosphohistidine is not the same compound as that involved in the labelling of ATP by the oligomycin-sensitive pathway. The synthesis of phosphohistidine involves succinyl-coenzyme *A*, the oligomycin-sensitive pathway the high-energy intermediates of oxidative phosphorylation. The P_i-ATP exchange is represented by a rapid oligomycin-sensitive reaction and a slower oligomycin-insensitive reaction. Phosphohistidine is involved in the latter. In the presence of oligomycin there is little discrepancy between the rate of labelling of ATP and of phosphohistidine[4]. Clearly all the data can be satisfactorily explained on the basis that phosphohistidine is an intermediate of the reaction catalysed by succinyl-coenzyme synthetase. Although protein-bound phosphohistidine, discovered by Boyer, is clearly a compound of great interest as an intermediate in certain enzyme-catalysed phosphorylation reactions, there is now no experimental evidence in support of the view that it is an intermediate of respiratory-chain phosphorylation.

Table 2. EFFECT OF ARSENITE AND ARSENATE ON THE INCORPORATION OF $^{32}P_i$ INTO PROTEIN-BOUND P AND INTO ATP

Addition	C.p.m. in Protein P	ATP	Ratio (%)
None	2,670	56,400	4·7
Arsenate (5 mM)	210	4,200	5·0
Arsenite (5 mM)	250	28,500	0·9

Procedure as in Fig. 2, ref. 4. 40 sec at 0°.

During the symposia before, during and after the International Congress of Biochemistry in New York, July 27–August 1, 1964, all participants, including Dr. Boyer, appeared to be in agreement with this conclusion. On the other hand, Dr. Boyer reiterated the objections to our kinetic argument[4] which he and his colleagues published shortly before the Congress[8]. Since our argument is applicable not only to the now-abandoned theory that phosphohistidine is an intermediate of respiratory-chain phosphorylation, but to any other compound which is to be brought forward as a possible phosphate-containing intermediate of respiratory-chain phosphorylation, we should like to reiterate our views and to discuss Boyer's objections to them.

The point under discussion is essentially the validity of kinetic criteria for distinguishing between possible reaction pathways in mitochondria. The use of ^{32}P to follow the pathway of phosphate in the synthesis of ATP is fundamentally similar to the use of spectroscopic methods to follow the pathway of electron transfer. When the passage of electrons from NADH to oxygen, catalysed by the Keilin and Hartree heart-muscle preparation, is inhibited by cyanide or by removal of oxygen, the uptake of electrons by cytochrome *b* is much slower than the rate of oxidation of NADH in the uninhibited system; this finding induced us to remove cytochrome *b* from the main respiratory chain for the oxidation of NADH in this preparation[10]. Chance[11], using a similar criterion, came to the same conclusion with respect to the oxidation of succinate by this preparation. Similarly, Redfearn[12] has questioned whether the reduction by succinate of ubiquinone in respiratory-chain preparations, which proceeds at 55–59 per cent of the rate of the overall reaction, is sufficiently rapid to permit ubiquinone to be placed on the main succinate oxidase chain. It should be pointed out, however, that in this case the discrepancy between the two rates is much less than in the experiments cited relating to cytochrome *b*. Moreover, Green[13] has pointed out that the ubiquinone, which is present in much larger concentrations than other components of the chain, may be kinetically inhomogeneous and that only about one-half of the total amount present may transfer electrons along the chain. In this case, then, there is good reason

to keep open the possibility that ubiquinone is on the main pathway, particularly since there is other evidence in favour of this view.

In our experiments[4], the maximum rate of labelling of phosphohistidine, both in the presence and the absence of oligomycin, was only 1·5 per cent of the maximal rate of labelling of ATP in the absence of oligomycin. Applying the same criteria as above, we conclude that phosphohistidine is not an intermediate in the formation of ATP.

Boyer and colleagues[1–3], on the other hand, by plotting, as a function of time, the percentage of maximum incorporation in phosphohistidine and ATP, obtained curves in which the former reached its maximum before the latter, and concluded that this is a sufficient criterion for a precursor-product relationship. In our view, it can be very misleading to plot the data in this way when the amount of product (ATP) is two orders of magnitude greater than the amount of the proposed precursor (phosphohistidine). To return to the comparison of the respiratory chain, incorrect conclusions on the relative rates of reduction of ubiquinone and cytochrome *b* would be drawn if one only measured the rate of changes of the degree of the reduction of these two compounds, without taking account of the much larger amount of ubiquinone present.

In their recent paper, Boyer *et al.*[8] claim to have demonstrated an initial lag in the incorporation of $^{32}P_i$ into phosphohistidine (3 sec at 0°, 5–15 msec at 25°). They conclude that other reactions or processes precede the phosphohistidine labelling, so that our results[4] "only suffice for estimation of a minimal value for the rate of phosphohistidine turnover. The actual rate could far exceed this minimal value. Thus nothing in the experimental findings rules out an exchange sufficiently rapid so that the specific activity of the phosphohistidine is close to the same as that of the P_i at the phosphorylation site(s) when the label is first detected in phosphohistidine. Under such circumstances, if the pools of phosphohistidine and ATP are catalytically homogenous, the participation of phosphohistidine as an intermediate would only demand that its rate of approach to maximal labelling equal or exceeds that of ATP. Such is observed to be the case. With demonstration of a readily anticipated lag in the labelling of phosphohistidine, the use of data on labelling rates in mitochondria to estimate turnover rates has no more validity than the attempted measurement of turnover rates of phosphorus compounds in tissues by measurement of rates of incorporation of intravenously administered $^{32}P_i$".

The analogy with experiments on the uptake of intravenously administered $^{32}P_i$ appears quite inappropriate. The difficulty with such experiments is that the rate-limiting step is often the uptake of $^{32}P_i$ by the tissues, so that the rate of incorporation of $^{32}P_i$ into intracellular phosphate compounds underestimates the phosphorylative capabilities of the cells. In the experiments with mitochondria, the end-product (ATP) is rapidly labelled.

Even if the small time-lag in the synthesis of phosphohistidine claimed by Bieber *et al.* exists (it is not clearly visible to us in their published results), this does not affect our conclusion drawn from the relative rates of uptake of $^{32}P_i$ into phosphohistidine and ATP during the zero-order portions of the curves. In fact, if the formula of Calvin and Duffield[14], which is often used by biochemists to calculate the rates of exchange from incorporation data, is applied to our data, the same discrepancy between the two rates is found, although the calculated rates of both incorporations vary with time, because the formula of Calvin and Duffield is based on first-order kinetics.

Experimental support for our view that the measured rates of incorporation have quantitative significance is given by the effects of arsenate and arsenite on these rates, shown in Table 2.

For these reasons, we wish to reaffirm our view that the criterion that a given compound is an intermediate in oxidative phosphorylation should be that the initial rate of its labelling from $^{32}P_i$ should not be less than the maximal rate of labelling of the product. As a model to test this postulate, we have chosen succinyl-coenzyme *A* synthetase. Since, in the complete system (succinyl-coenzyme *A*, P_i, GDP and GTP), the steady-state level of protein-bound phosphohistidine is too low to allow reliable measurements of the rate of incorporation of $^{32}P_i$ into the phosphohistidine, this was measured in the absence of GDP or GTP. This corresponds to the situation where a possible intermediate of respiratory-chain phosphorylation is tested in the presence of oligomycin. In Fig. 1, the rate of incorporation of $^{32}P_i$ into phosphohistidine, in the absence of GDP or GTP, is compared with the rate of incorporation into GTP when GDP and GTP were added. It may be seen that the initial rate of incorporation into the phosphohistidine is about the same as that into the GTP in the overall system. This is consistent with the suggestion[6,7] that protein-bound phosphohistidine is an intermediate in this reaction.

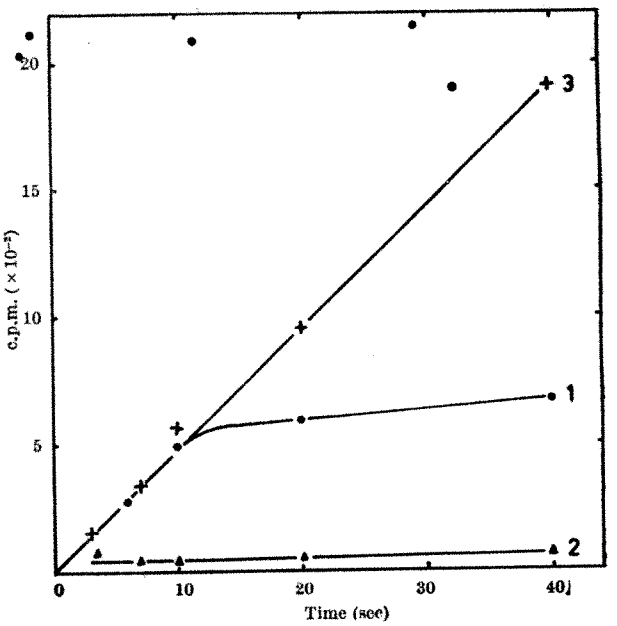

Fig. 1. Incorporation of $^{32}P_i$ into protein-bound phosphohistidine of succinyl-coenzyme *A* synthetase under different circumstances. The reaction mixture contained 5 mM $MgCl_2$, 1 mM EDTA (*p*H 7·4), 6 mM KCl, 100 mM *tris*-HCl buffer (*p*H 7·4), 70 μM potassium phosphate (*p*H 7·4), 200 mM sucrose, 0·17 mM succinyl-coenzyme *A* and 5 mg of a crude preparation of succinyl-coenzyme *A* synthetase[8] in a final volume of 1·3 ml. In curves 2 and 3, 0·08 mM GDP and 0·8 mM GTP were also present. After 15 min at 0° the reaction was started by addition of 0·1 μmole $^{32}P_i$ ($1·5 \times 10^6$ c.p.m.) and different samples stopped at different time intervals by the addition of 8·0 ml. of a solution 0·3 M in trichloroacetic acid and 3 mM in potassium phosphate and by 0·2 ml. 40 per cent trichloroacetic acid, respectively. Curves 1 and 2 give the incorporation into protein-bound phosphohistidine, measured by the method of Bieber *et al.*[5]. Curve 3 gives the incorporation into GTP measured as the activity in the protein-free supernatant after removal of $^{32}P_i$ as phosphomolybdate into benzene-isobutanol

There remain for discussion other criticisms brought forward by Bieber *et al.*[8].

(1) They suggest that the limited labelling of mitochondrial ATP which we observed at 0° might not occur by the main reactions of oxidative phosphorylation. Since, however, the labelling which we study at 0° is almost completely sensitive to oligomycin, we consider that it is related to oxidative phosphorylation. Furthermore, the high-energy intermediates of oxidative phosphorylation are readily utilizable at 0° for the reversal of the respiratory chain[15] and for ion uptake[16]. In any event, the kinetic data of Bieber *et al.*[8] obtained at 25° are in essential agreement with our own.

(2) Bieber *et al.*[8] point out that the lack of inhibitory effect of oligomycin on phosphohistidine is not conclusive, since the mode of action of oligomycin is not known.

For example, it might prevent the transfer of a phosphorylated intermediate from a hydrophobic locus, where it is formed, to a locus allowing reaction with ADP. We agree that lack of inhibition by oligomycin of the incorporation of $^{32}P_i$ into phosphohistidine is not conclusive evidence, of itself, against the participation of phosphohistidine as an intermediate in ATP synthesis, and, contrary to what Bieber *et al.* write, we did not use this argument, since the possible explanation given by them had been pointed out to us by Dr. J. B. Chappell. The only assumption which we have made is that oligomycin prevents phosphorylation of ADP, a fact which is well established and which we demonstrated under our experimental conditions.

(3) Bieber *et al.*[8] suggest further that more than one form of bound phosphohistidine may be present, with an oligomycin-insensitive form as the principal component observed under the experimental conditions used. If a second, oligomycin-sensitive phosphohistidine is present, it has not yet been revealed experimentally, since the amount of phosphohistidine labelled at isotopic equilibrium is not decreased by addition of oligomycin. Although the possibility that a small amount of phosphohistidine, undetectable so far, might be an intermediate in respiratory-chain phosphorylation, cannot be excluded, this postulate is at present pure speculation, without any experimental basis. The total amount of protein-bound phosphohistidine in rat-liver mitochondria is only about 0·05 μmole/g mitochondrial protein[1], rather less than that of the individual cytochromes.

The fact that phosphate strongly inhibits arsenate-stimulated mitochondrial respiration in the absence of ADP is rather good evidence that a relatively stable ~P compound is an intermediate in oxidative phosphorylation[17]. The method introduced by Boyer is the most direct way of searching for this compound. It is our view that it is necessary to show that the rate of labelling of any compound proposed as a ~P intermediate should be of the same order as the rate of labelling of the ATP and that its labelling should show the susceptibility to inhibitors expected from studies of oxidative phosphorylation with intact mitochondria.

We thank Mr. R. Stoeckart for his collaboration and assistance in many of the new experiments reported. We also thank Dr. J. M. Tager for his advice.

ELUCIDATION OF THE BIOSYNTHETIC PATHWAY OF THYROIDAL 3:5:3′ TRIIODOTHYRONINE BY MEANS OF ISOTOPE POSITION EXPERIMENTS

By Dr. L. G. PLASKETT and Dr. C. F. BARNABY

Department of Biochemistry, University of Edinburgh Medical School, Edinburgh 8, and Medical Research Council Department of Clinical Research, University College Hospital Medical School, London, W.C.1

So far only two theoretically probable routes for triiodothyronine biosynthesis have been proposed. Gross and Pitt-Rivers[1] suggested that it might arise by removal of one iodine atom from thyroxine. Roche, Michel, Michel and Lissitzky[2], being unable to demonstrate deiodination of thyroxine by thyroid slices, concluded that the biosynthesis probably involved coupling between one molecule each of mono- and di-iodotyrosine. The evidence of Pitt-Rivers[3] supporting the latter hypothesis must now be regarded as questionable because the triiodothyronine isolated for specific radioactivity measurements by that author is known to have been contaminated by another component[4]. This leaves the problem of triiodothyronine biosynthesis undecided at the present time.

The work of Plaskett[5,6] showed that in theory the biosynthetic pathway of triiodothyronine could be determined by studying the way in which iodine-131 is distributed between the rings of triiodothyronine in the thyroid gland during the early intervals after administering [^{131}I]-iodide. This possibility exists because if triiodothyronine is derived from thyroxine, then both the iodine-containing rings of triiodothyronine would be derived from the same precursor, namely diiodotyrosine, which is the sole precursor of thyroxine[7,8]. In this case, therefore, one must expect that even at the shortest times after administration of [^{131}I]-iodide the two rings of triiodothyronine will be labelled at equal specific activity with ^{131}I.

Alternatively, if triiodothyronine arises by the coupling of one molecule each of mono- and di-iodotyrosine, then the two rings have different precursors. In a situation in which the precursors have different specific radioactivities the iodine on the two rings of triiodothyronine will become unequally labelled with ^{131}I.

This theoretically predicted situation is illustrated in Fig. 1.

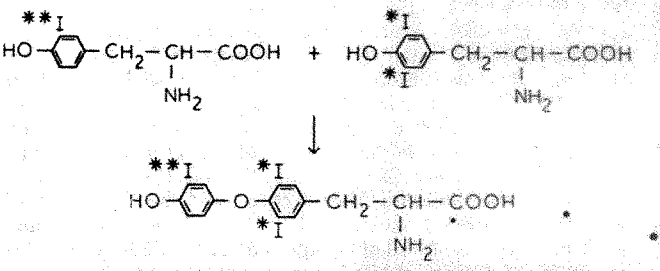

Fig. 1. Suggested scheme for triiodothyronine biosynthesis

We have been working for some time with the view of finding out which of these pathways applies *in vivo* in the rat thyroid gland. Some results have already been published and include: (1) confirmation that thyroxine, as predicted by theory, is always equally labelled in the two rings after administration of [^{131}I]-iodide[6]; (2) develop-

Table 1. Incorporation of [^{131}I] into Monoiodotyrosine and Diiodotyrosine in the Rat Thyroid Gland at Different Times following Administration of ^{131}I-iodide

Time after administration of [^{131}I]-iodide	No. of determinations	Total thyroid gland radioactivity (%) Monoiodotyrosine	Diiodotyrosine	*R* value, i-e [^{131}I]-monoiodotyrosine [^{131}I]-diiodotyrosine
30 min	8	34·7 ± 0·4*	43·4 ± 0·3	0·80
1 h	6	32·9 ± 0·3	42·7 ± 0·3	0·77
24 h	11	22·4 ± 0·3	45·4 ± 0·4	0·50

Table 2. Distribution of ^{131}I between the Rings of 3 : 5 : 3′ Triiodothyronine (*T*3) isolated from the Thyroid Glands of Rats at Different Times following Administration of [^{131}I]-iodide. Random labelling would correspond to 66·7 per cent of ^{131}I on the 3 : 5 Positions. The Value predicted on the Basis of the Hypothesis that *T*3 arises from Thyroxine would be 66·7 at all Times examined

Time after administration of [^{131}I]-iodide	*R* value	No. of degradations performed	% of ^{131}I on the 3 : 5 positions: Value found	Value predicted for newly formed *T*3 on the basis of the *R* value and the hypothesis that *T*3 arises from monoiodotyrosine and diiodotyrosine
30 min	0·80	12	56·5 ± 0·6	55·6
1 h	0·77	6	55·7 ± 1·2	56·5
24 h	0·50	15	65·4 ± 1·0	66·7

ment of a chromatographic technique for isolation of triiodothyronine from the thyroid gland at a high level of radiochemical purity[4,5]; (3) development of a degradation procedure for triiodothyronine which permits investigation of the distribution of ^{131}I between the rings[5].

Unlike many other workers[3,9,10] our experimental conditions were such that we were unable at first to produce a situation in which the specific radioactivities of monoiodotyrosine and diiodotyrosine were different[11]. This difficulty has been overcome recently by feeding the animals with commercial rat pellets instead of the powdered low-iodine diet formerly used. It is now known that in rats fed the pellet diet, the specific radioactivity of iodine in monoiodotyrosine is considerably greater than that in diiodotyrosine at 30 min after the dose of [^{131}I]-iodide. The specific radioactivities of the two compounds become increasingly similar at later times and are the same at 24 h[12]. This effect is shown in Table 1, which gives the results of analysis of rat thyroid tissue at 30 min, 1 h, and 24 h after administration: the diminution with time in the value of the ratio *R*, of ^{131}I-monoiodotyrosine to [^{131}I]-diiodotyrosine, shows that the monoiodotyrosine was initially the more heavily labelled. The value of *R* does not undergo any significant change at times later than 24 h, the value measured at 38 h being 0·49. Fig. 2 illustrates the change in the value *R* with time in an experiment with a single rat which received ^{125}I 24 h before death followed by ^{131}I 30 min before death. On death the thyroid gland was removed, homogenized and hydrolysed enzymatically; three single-dimensional chromatograms, each measuring 38 cm from origin to solvent front, were run with the hydrolysate. After development the chromatograms were cut into thirty-eight 1-cm segments and each segment was assayed for both ^{125}I and ^{131}I. Fig. 2 shows the mean results of these assays. It can be seen that iodide was very much more heavily labelled with ^{131}I than with ^{125}I. Monoiodotyrosine was also more heavily labelled with ^{131}I than with ^{125}I. The most important fact emerging in relation to the present work is that the labelling situation for the two iodotyrosines is opposite. Monoiodotyrosine contained 18·6 per cent of the total ^{131}I and 17·2 per cent of the total ^{125}I. Diiodotyrosine contained 36·2 per cent of the ^{131}I and 45·4 per cent of the ^{125}I. Monoiodotyrosine is thus a rapidly labelled component and diiodotyrosine is a relatively slowly labelled component of thyroid tissue.

From this double isotope experiment and from the evidence of measurements of *R* in rats given ^{131}I (Table 1) we are now able to suggest, in common with workers in other laboratories[3,10], that the rats used go through a period following injection of ^{131}I-iodide during which the two iodotyrosines in the thyroid gland have different specific radioactivities.

This finding has made the determination of the pathway of triiodothyronine biosynthesis possible. It is clear that if the biosynthesis occurs by coupling between one molecule each of mono- and di-iodotyrosine, then it is likely that at 30 min or 1 h after a dose of ^{131}I-iodide the two rings of triiodothyronine will be found to be labelled unequally with ^{131}I.

In the present work samples of triiodothyronine have been isolated from rat thyroid glands at 30 min, 1 h, and 24 h after administration of [^{131}I]-iodide and degraded by the diazo-coupling technique[5] to determine the distribution of label between the rings. The isolation procedure consisted of two-dimensional chromatography in the solvent systems butan-1-ol/dioxan/aq. 2 N-ammonia (4 : 1 : 5) (first) and butan-1-ol/aq. 9 N-ammonia (1 : 1) (second). Location of the triiodothyronine spot was determined by autoradiography and by reference to a spot of carrier triiodothyronine detected during brief exposure under an ultra-violet lamp. The result shows conclusively that at 30 min and 1 h after the dose the β-ring iodine atom of triiodothyronine (position 3′) is labelled more heavily than the iodine on the α-ring

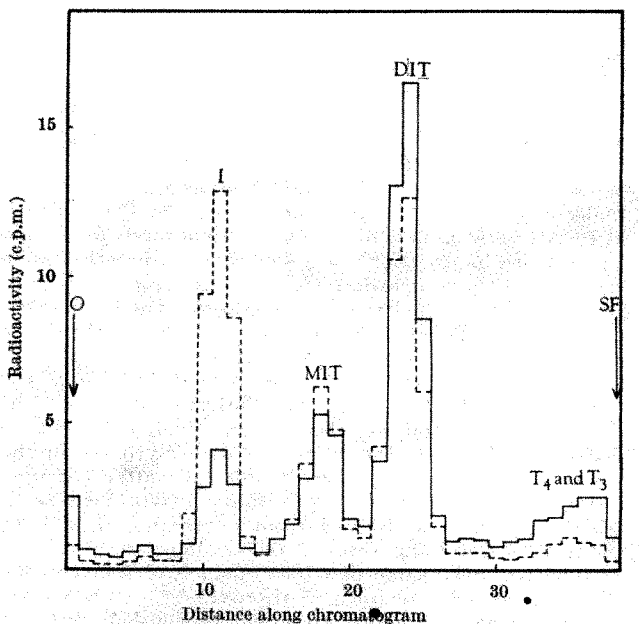

Fig. 2. Chromatogram scan of a rat which received ^{125}I 24 h before death followed by ^{131}I 30 min before death. ·-·-·-·, ^{125}I; ———, ^{131}I; *O*, origin; I, iodide; MIT, monoiodotyrosine; DIT, diiodotyrosine; T_3, triiodotyrosine; T_4, thyroxine; SF, solvent front

(positions 3 and 5) (Table 2). This is consistent with origin of the β-ring from monoiodotyrosine and origin of the α-ring from diiodotyrosine. Furthermore, it appears to be incompatible with an origin of triiodothyronine from thyroxine. It is predicted by theory and has been shown experimentally[6] that thyroxine in the rat thyroid is labelled equally on the two rings at all time-intervals studied following administration of [^{131}I]-iodide. Therefore, if thyroidal thyroxine is homogeneous with respect to turn-over the triiodothyronine isolated in the present work cannot have arisen from thyroxine.

The question arises as to whether this constitutes an unequivocal demonstration that triiodothyronine is formed by the coupling of mono- and di-iodotyrosine. At the present time we can see only two possible objections.

(1) Several workers including ourselves have recently obtained evidence suggesting that thyroglobulin may be heterogeneous with respect to turn-over[11,13,14]. While this has not yet been shown definitely to apply to the thyroxine-containing fraction, the possibility that it may do so should be taken into account. The likelihood that this would affect the conclusions of the present work must be considered.

In theory the precursor of triiodothyronine may be a fraction of the total thyroxine in a separate metabolic pool in which preferential labelling of the β-ring occurs. However, the mean distribution of ^{131}I between the rings of thyroxine is known always to be such that the two rings are equally labelled; therefore, the existence of a separate pool of this type would necessitate the existence of a second separate pool of thyroxine in which the degree of preferential labelling was at all times exactly equal but opposite to that in the first. This would seem to require a degree of coincidence of unlikely events that makes it extremely improbable.

(2) The evidence presented here in favour of the coupling of mono- and di-iodotyrosine in triiodothyronine formation is, first, that the isotopic data are compatible with this mechanism, and, secondly, there are no alternative hypotheses. The second of these pieces of evidence is negative in character and cannot exclude as yet unconceived hypotheses which would give rise to the experimentally-determined labelling pattern.

In spite of these two theoretical objections it is our opinion that the evidence of the present paper establishes, beyond reasonable doubt, the pathway of triiodothyronine biosynthesis as the coupling between one molecule each of mono- and di-iodotyrosine.

ISOLATION OF A HIGHLY PURIFIED ENCEPHALITOGENIC PROTEIN FROM BOVINE CORD

By Dr. ROBERT F. KIBLER, RICHARD H. FOX and Prof. RAYMOND SHAPIRA

Departments of Medicine and Biochemistry, Emory University School of Medicine, Atlanta, Georgia

EXPERIMENTAL allergic encephalomyelitis (EAE) has been produced by both proteolipid and water-soluble, basic, protein fractions of central nervous system tissue. Encephalitogenic activity of proteolipids in rabbits was demonstrated by Waksman *et al.*[1], whereas basic protein but not proteolipid was shown to be encephalitogenic in guinea-pigs by Kies and Alvord[2]. Kibler and Barnes[3] later demonstrated EAE activity of a basic protein fraction in rabbits. This article describes the isolation of a highly purified, low-molecular-weight, encephalitogenic protein from a water-soluble, basic, protein fraction of bovine cord.

Fresh, whole bovine spinal cord was freed of its meninges and stripped clean of its grey matter. 140 g were homogenized in 300 ml. cold (−20° C) acetone for three 1-min periods at high speed in a Servall 'Omni-mixer' (Ivan Sorvall, Inc.). An additional 900 ml. of cold acetone were added and extraction was continued with constant mixing by a magnetic stirrer for 10 min at −12° C. The residue was taken to near dryness on a Buchner funnel and extracted in 700 ml. of 1 : 1 acetone, ethyl ether for 5 min at −12° C. The latter extraction was repeated three additional times and after the last filtration the residue was dried by gentle melding with a spatula on large pieces of blotting paper. Approximately 30 g of a coarse, beige-coloured powder were obtained. This powder was extracted for 24 h in 400 ml. of 0·1 M sodium citrate, *p*H 4·3 at 4° C with constant stirring. The suspension was spun at 12,800*g* in a high-speed centrifuge (Model *AX*, Lourdes Instrument Corp.) in the cold room, but complete clearing of the supernatant was not achieved. The supernatant was dialysed against distilled water at 4° C for 24 h in 1-in. dialysis tubing (Visking Corp.) with 2 changes of the dialysate. The supernatant now was easily cleared by spinning at 500*g* in a refrigerated centrifuge (model *PR-2*, International Equipment Co.) at 4° C. Lyophilization yielded an average of 500 mg of a fine white powder.

100 mg of this water-soluble protein fraction (WSPF) were chromatographed on a 3-g carboxymethylcellulose ((CMC) 0·9 ± 0·1 m.equiv./g, Mann Research Lab.) column in an airless system and at a constant flow rate. The materials and techniques employed in this method were the same as those previously described for the chromatography of bovine pancreatic ribonuclease[4] with the exception that no condenser jackets were used with the columns and the procedure was carried out at room temperature. A linear gradient was provided by adding 400 ml. of 0·005 M borate buffer, 0·05 M NaCl to the mixing flask and 400 ml. of 0·005 M borate buffer, 0·4 M NaCl to the second flask. Both solutions were adjusted to *p*H 8·6. Fractions between 2·0 and 2·4 ml. were collected every 17 min and frozen before reading at 280 mμ in a Beckman *DU* spectrophotometer.

The chromatographic pattern of the WSPF is shown in Fig. 1. Two major, symmetrical peaks were observed; peak 1, tubes 10–16, and peak 2, tubes 50–56. Peak 1, after dialysis and lyophilization, yielded 15 mg and consisted of 4 bands on disk polyacrylamide gel electrophoresis, *p*H 4·4 (ref. 5), and was inactive in rabbits in a dose of 200 γ/animal. Since overnight dialysis of peak 2 resulted in a major loss of the protein, the peak was first

lyophilized and then desalted on a *G–25*, coarse, beaded 'Sephadex' (Pharmacia, Uppsala, Sweden) column, 2·1 cm in diameter and 54 cm high. The 'Sephadex' was equilibrated with 0·01 N HCl and this same solution was used to elute the protein by simple gravity flow. 4 ml. fractions were collected every 30 sec and read at 280 mμ in the Beckman *DU* spectrophotometer. The protein came through as a single, symmetrical peak at the end of the void volume, that is, tubes 14–17. Lyophilization yielded 7–10 mg of a fine, white powder. This material proved to be highly purified by electrophoretic and ultracentrifuge analysis.

Fig. 2 shows the pattern of 50γ each of the WSPF and the CMC 2nd peak on disk polyacrylamide-gel electrophoresis, *p*H 4·4. The WSPF pattern consists of 4 minor and 5 major bands while the CMC 2nd peak shows two faint minor bands and a single major band corresponding in position to one of the major bands of the WSPF. On disk polyacrylamide-gel electrophoresis, *p*H 2·3 (*Chemical Formulation for Disc Electrophoresis*, Canalco), there was considerably less resolution of the WSPF, but the CMC 2nd peak pattern was similar to the pattern at *p*H 4·4 with the exception that the two minor bands were more distinct. The ultracentrifuge pattern of the CMC 2nd peak is shown in Fig. 3. A 1·0 per cent solution of the protein in phosphate buffer, *p*H 6·9, was placed in a valve-type, synthetic boundary cell and centrifuged at 59,800 r.p.m. at 18° C. The frame on the left was taken at the time full speed was first reached and the frame on the right 48 min later. The sedimentation constant calculated from the distance the peak of the ascending limb moved in 48 min was $0{\cdot}42 \times 10^{-13}$, which suggests that the molecular weight of the 2nd peak protein may be less than 10,000. The slight asymmetry and thickening of the descending limb in the frame taken at 48 min indicate contamination with one or more heavier molecular species.

The encephalitogenic activity of this material was tested in male albino rabbits, 12–14 weeks of age. The materials and methods used in these investigations were similar to those reported in previous experiments with a water-soluble, basic protein fraction of rabbit cord[3].

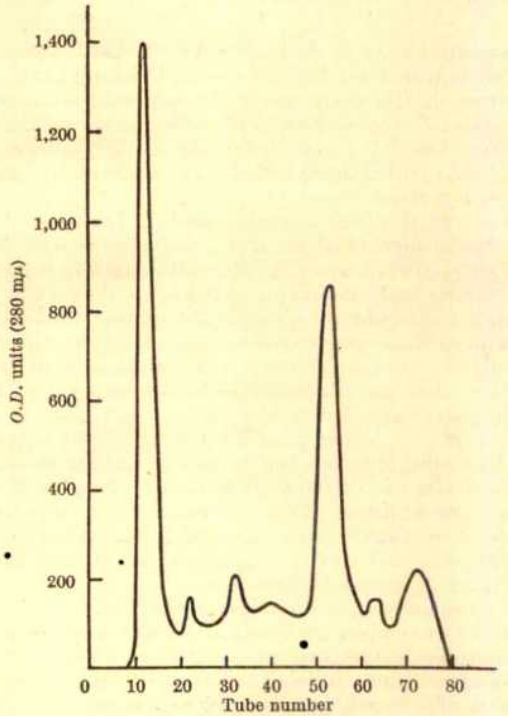

Fig. 1. Column chromatography of the WSPF on CMC. A linear gradient consisted of 400 ml. of 0·005 M borate buffer, 0·05 M NaCl in the mixing flask and 400 ml. of 0·005 M borate buffer, 0·4 M NaCl in the second flask. Both solutions at *p*H 8·6

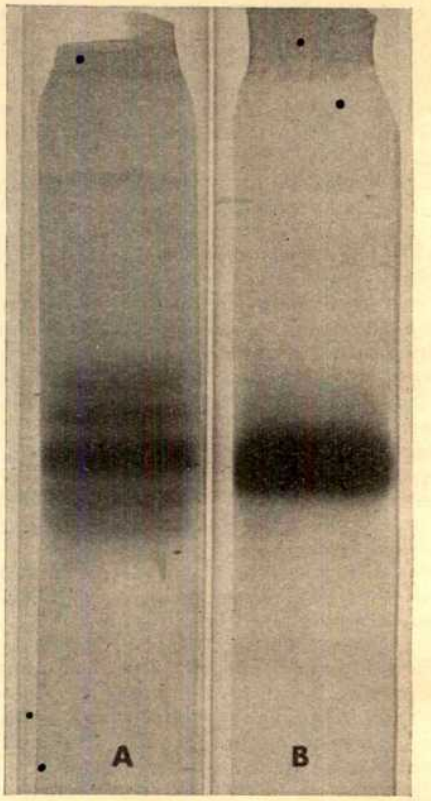

Fig. 2. Disk polyacrylamide gel (0·5 cm × 6·5 cm) electrophoretic patterns of the WSPF (*A*) and CMC 2nd peak (*B*) at *p*H 4·4

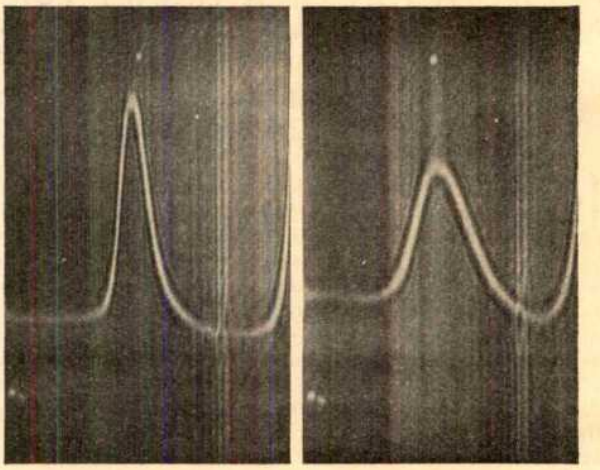

Fig. 3. Ultracentrifuge pattern of the CMC 2nd peak. On the left is the pattern at the start and on the right the pattern after 48 min of centrifugation at 59,800 r.p.m. at 18° C

A 1 : 1 ratio of oil (Difco incomplete adjuvant) to water and a 3 : 1 ratio of *Mycobacterium butyricum* to protein were used. Each rabbit received 0·25 ml. of the emulsion intradermally, equally divided between the 4 foot-pads.

Table 1 shows the results obtained with the CMC 2nd peaks from five different WSPF preparations. Preliminary experiments suggested that the CMC 2nd peak protein reached maximal activity around 200γ. In these investigations 200γ produced experimental allergic encephalomyelitis (EAE) in 100 per cent of 31 rabbits with an average day of onset of 14·5 days after challenge. Two of the rabbits had mild disease, that is, either had incomplete hind-leg paralysis or developed complete paralysis after more than a 4-day interval following onset. Sections of the spinal cord from two randomly selected rabbits

Table 1. ENCEPHALITOGENIC ACTIVITY OF THE CMC 2ND PEAK PROTEIN COMPARED TO THE WSPF AND TO WHOLE BOVINE CORD

Antigen		Dose	Incidence of EAE	Day of onset Range	Day of onset Mean	No. with mild disease
CMC 2nd peak WSPF prep.	72	200 γ	5/5	13–20	15·4	0/5
	80	200 γ	5/5	14–17	15·0	1/5
	81	200 γ	5/5	13–16	14·4	0/5
	83	200 γ	5/5	13–19	14·8	0/5
	85	200 γ	6/6	13–14	13·5	1/6
			26/26		14·5	2/26
WSPF prep.	81	500 γ	6/12	13–21	16·0	3/6
Whole cord		250 mg	24/25	11–17	12·7	2/24

showed the typical histological features of EAE. For comparison the activity of a representative WSPF preparation and whole bovine cord is also shown in Table 1. The injection of the WSPF was handled in the same manner as the CMC peaks. With the whole cord injections a 1 : 1 ratio of oil to cord was used and each rabbit received a total of 0·5 ml. of the emulsion containing 5·0 mg *Mycobacterium butyricum*. 500γ of the WSPF caused disease in 6 of 12 rabbits, with mild disease in 3, and an average interval to onset after challenge of 16·0 days. Comparable results for 250 mg whole cord were a disease incidence of 24/25 with mild disease in 2 and a 12·7 average day of onset.

Although the CMC 2nd peak protein was considerably more encephalitogenic than the WSPF, it did not quite display the full activity of whole cord. This is apparent from the average day of onset, an important quantitative index of encephalitogenic activity[6]. The difference between 12·7 and 14·5 days is highly significant, and similar differences have been a consistent feature of experiments prior to and subsequent to the present ones. As already indicated, 200γ of the CMC 2nd peak protein seems to represent a maximally active dose. Doses up to 500γ do not enhance the day of onset. This could mean that the purified protein is an incomplete antigen or only one of several antigens. There is also the possibility that the lipid content of whole cord enhances the adjuvant effect of the water-in-oil emulsion. In any event, the high degree of encephalitogenic activity and chemical purity of the CMC 2nd peak protein makes it a very desirable antigen for future investigations in EAE.

The small molecular size of the CMC 2nd peak protein suggests that it may be similar to the dialysable peptide reported to produce EAE in guinea-pigs by Robertson *et al.*[7]. A highly purified, dialysable preparation of bovine cord with encephalitogenic activity in guinea-pigs has also been reported by Nakao and Einstein[8].

This work was supported by a research grant from the U.S. National Multiple Sclerosis Society.

β-LACTOGLOBULINS

By K. BELL and DR. H. A. McKENZIE

Sir William McGregor School of Physiology, University of Queensland, Brisbane, and the Department of Physical Biochemistry, Institute of Advanced Studies, Australian National University, Canberra

MILK is the natural food of the new-born mammal and it must be well balanced to serve as the sole nourishment. The needs of the young vary considerably from species to species, and it is not surprising to find marked variation in the composition of milks of various species. Furthermore, the composition of the milk of a given species varies with the stage of lactation. Under natural conditions milk passes directly from mother to offspring. In the case of man successful lactation is not necessary for survival: substitute milks are readily available. However, numerous problems arise in their use. It is not surprising, therefore, that most attention has been given to the properties and composition of the most common substitute, cow milk.

It is the purpose of the present article to summarize studies which we have carried out over the past seven years on the β-lactoglobulins of milk of a number of different species. The unusual properties of these proteins make them of interest from the physico-chemical as well as the biological point of view. Our findings are considered in relation to those of other workers.

Bovine β-Lactoglobulins

The main whey proteins of mature bovine milk are: β-lactoglobulin (about 0·3 g/100 ml.), α-lactalbumin (about 0·1 g/100 ml.), serum albumin (about 0·04 g/100 ml.) and immune globulin (about 0·08 g/100 ml.)[1]. The predominant protein, β-lactoglobulin, was first crystallized by Palmer[2] in 1934. Sørensen and Palmer[3] showed that a 3-fold variation in the amount of solid phase did not appreciably change its solubility. These observations led to the conclusion that β-lactoglobulin was a pure protein. Thus it became a favourite protein for study by biochemists and chemists. McMeekin and Warner[4], using the X-ray data of Crowfoot, calculated an anhydrous molecular weight of 35,800 in agreement with values obtained by other methods.

The first real indication of the possible heterogeneity of β-lactoglobulin prepared from pooled milk came in 1946 from the heterogeneity studies of Li[5]. In 1955 Ogston and Tilley found differences in samples prepared from milks of individual cows. The main cause of these differences was the subject of an important discovery by Aschaffenburg and Drewry[6]. They found that β-lactoglobulin from pooled cow milk is a mixture of two genetically different proteins (*A*, *B*) and showed that some cows produce only β-lactoglobulin-*A*, others only β-lactoglobulin-*B* and the rest a mixture of the two proteins in approximately equal amounts.

Aschaffenburg and Drewry distinguished the two proteins by the difference in their mobilities during electrophoresis of the 'lactalbumin' fraction on filter paper at *p*H 8·6 (the β-lactoglobulin of higher mobility being designated *A*). Since then considerable development of methods of zone electrophoresis of higher resolution has occurred. One of us (K. B.) initiated an investigation of bovine milk using the method of starch-gel electrophoresis, to determine more precisely what genetic variants of β-lactoglobulin were present. This work has led *inter alia* to the detection of an additional variant[7] which has been designated β-lactoglobulin-*C*. The details of the method developed for typing of whey proteins will be given in detail elsewhere. It suffices to point out here that the method enables typing to be

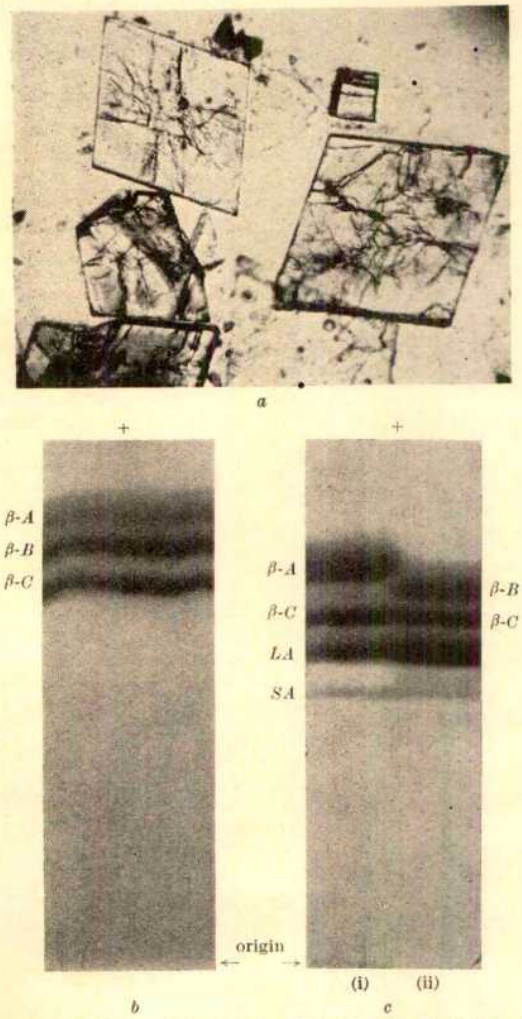

Fig. 1. (*a*) The first crystals of bovine β-lactoglobulin-*C* isolated in 1962 (× *c.* 60). The crystals are very fragile. (*b*) Starch-gel electrophoresis patterns of a solution of the three crystalline homozygous bovine β-lactoglobulins (*A*, *B*, *C*) at *p*H 8·5 (0·028 M H_3BO_3–0·012 M NaOH buffer), 7·5 V cm^{-1}, 5 h. (*c*) Patterns of 'lactalbumin' solutions from milks containing (i) β-lactoglobulin-*AC*, (ii) β-lactoglobulin-*BC*, under similar conditions to (*b*)

carried out on skim milk without prior separation of the casein group of proteins; it is more rapid than the filter paper method of Aschaffenburg and Drewry and gives superior resolution.

Occurrence and genetic implications. One of us (K. B.) has examined milks of 928 'pure bred' cows of five breeds (Jersey, Guernsey, Australian Illawarra Shorthorn, Friesian, Ayrshire) and has found that either β-lactoglobulin *A*, *B* or *C* occurs, singly or together with either of the other two proteins in the milks of individual cows in approximately equal concentrations. (In a preliminary communication it was thought that *A*, *B* and *C* could occur together but this result was artefactual and the explanation of it will be given elsewhere.)

Genetic investigations showed that the genes controlling the β-lactoglobulin synthesis were autosomal alleles.

In contrast to our work, Moustgaard *et al.*[8], using a different method of starch-gel electrophoresis, failed to detect type *C* in the milks of 158 Danish Jersey cows. It was considered of interest to determine if β-lactoglobulin-*C* has originated from a mutation in Australian Jersey cattle. In 1963 we provided a sample of β-lactoglobulin-*C* to Dr. R. Aschaffenburg, for use as a reference in looking for the possible occurrence of β-lactoglobulin-*C* in British cattle. In a random sample of 80 milks from British Jersey cows he found only two milks containing *C*: these were heterozygous (*BC* and *AC*). Thus β-lactoglobulin-*C* has not originated from an Australian mutant. Recently, Aschaffenburg[9] has demonstrated a similar polymorphism for bovine β-casein, three genetic variants (*A*, *B*, *C*) occurring in major British breeds. The third variant (*C*) was found only in the milk of Guernsey cows. Aschaffenburg suggested that if the β-casein allele is of ancient origin, it could be used in determining differences in the origins of Jersey and Guernsey cattle. If the β-lactoglobulin-*C* allele is restricted to Jerseys, as the present results indicate, and is of ancient origin, it could be used also in determining differences in the origins of the Channel Island breeds.

Isolation. In 1962 an attempt was made by one of us (H. McK.) to isolate β-lactoglobulin-*C* from the milk of a homozygous Jersey cow, using a method essentially similar to that developed by Aschaffenburg and Drewry for types *A* and *B*. It was found difficult to crystallize type *C*, but finally a successful procedure for crystallization was developed. The first crystals obtained in August 1962 are shown in Fig. 1*a*. During October 1962 we obtained crystals[10] from the milk of another homozygous cow using method 1 of two methods for isolation of β-lactoglobulins developed by Armstrong and McKenzie[11]. Since then β-*C* has been prepared some dozen times using both methods 1 and 2. Its properties[10] will now be compared with those of β-*A* and β-*B*.

Electrophoresis. On starch-gel electrophoresis at *p*H 8·6 β-*A* is the fastest-moving type, followed by β-*B* and then β-*C* (Fig. 1*b* and *c*). Since their particle sizes are similar under these conditions the differences arise from differences in mobility rather than a molecular sieving effect. It was expected, therefore, that a similar difference would be found in electrophoresis in agar (ion agar and agarose), acrylamide and on filter paper. The expected separation has been found with these methods. However, the concentration at which the protein is applied is of considerable importance.

Molecular size. Ogston and Tombs showed by sedimentation studies that β-lactoglobulin-*A* associated at *p*H 4·7 and low temperature[12]. Timasheff and Townend[13] confirmed this association between *p*H 3·5 and 5·2 by light-scattering measurements and showed that it was rapid, reversible and highly specific, giving a 'tetramer' of particle weight 4 × 35,500. They found that these samples of β-lactoglobulin-*A* contained 10 per cent of a non-associating component. On the other hand, while McKenzie and Smith found a similar association of *A* to form 'tetramers' from sedimentation investigations (velocity and Archibald), they did not find any evidence of a non-associating component in their samples[14–16]. In 1963 we supplied a sample of our β-lactoglobulin-*C* and information on its occurrence to Dr. R. Townend at his request for him to check if his samples of *A* and *B* lactoglobulin were contaminated with *C*. Townend *et al.* concluded that their *A* and *B* samples were free of *C*. We understand they have since isolated *C* from an American herd and confirmed some of our results.

Timasheff and Townend[17] observed that below *p*H 3·5 both *A* and *B* β-lactoglobulins dissociated into particles of molecular weight 17,750. Other evidence would seem to indicate that the units from a given type are identical single chains, but that the type *A* chain is different from that of type *B* (ref. 18). Hybridization experiments show that reassociation can only occur specifically and no β-*A* *B* hybrids are formed[18].

Tanford and Nozaki have shown from *p*H titration curves that β-*A* has two more free carboxyl groups than *B* per 35,000 particle weight[19]. Timasheff and Townend[17] showed that maximal association of β-*A* occurred at *p*H 4·7, which is in the *p*H range of side-chain carboxyl ionization. These findings suggest the possibility of the extra aspartic acid residues known to be in β-*A*, being involved in the association. Recently, Armstrong and one of us (H. McK.)[20] have blocked the carboxyl groups in

β-*A* using a method developed by Armstrong for blocking carboxyl groups in proteins. This blocking prevents the association occurring. This work implicates strongly the role of the side-chain carboxyls of the extra aspartic acid residues in β-A being involved in its tetramerization. The significance of this work will be discussed in detail elsewhere.

We have found that in its association–dissociation β-*C* resembles β-*B* and not β-*A*.

Amino-acid composition. Dr. D. C. Shaw has collaborated with us in examining the chemical differences between the three types[21]. Amino-acid analyses of the HCl hydrolysate show that, for a monomer molecular weight of 17,800, β-*A* has the following residue differences compared with β-*B*: +1 aspartic acid residue −1 glycine, −1 alanine and +1 valine. (These differences for *A* and *B* are similar to those reported by Piez *et al.*[22] and Gordon *et al.*[23]). The amino-acid composition of type *C* is similar to type *B*, having no difference in aspartic acid, glycine, alanine and valine, but it is different from *B* in showing a difference of +1 histidine, and −1 glutamic acid residues. In the protein the glutamic acid residue may occur as glutamine. Two-dimensional electrophoresis of the tryptic hydrolysate from performic acid oxidized β-*C* confirmed the existence of three histidine-containing peptides whereas β-*B* has only two.

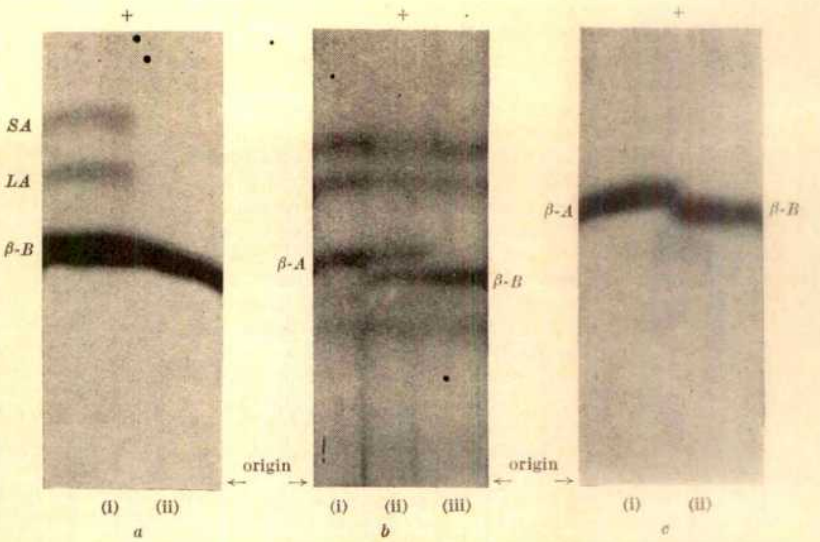

Fig. 2. (*a*) Starch-gel electrophoresis patterns of (i) sheep 'lactalbumin' solution containing β-lactoglobulin-*B* and (ii) of the isolated sheep β-lactoglobulin-*B*, at *p*H 7·6 (*I* 0·2, phosphate buffer), 7·5 V cm^{-1}, for 5 h. (*b*) Patterns of sheep skim milks containing (i) β-lactoglobulin-*A*, (ii) β-lactoglobulin-*AB* and (iii) β-lactoglobulin-*B*, at *p*H 7·6, 6·5 V cm^{-1} for 5 h. (*c*) Patterns of the isolated sheep β-lactoglobulins (i) β-*A*, (ii) β-*B*, similar conditions to (*a*)

Optical rotatory properties. The β-lactoglobulins exhibit unusual optical rotatory properties. Many proteins show co-variance of the rotatory parameters characteristic for a simple mixture of helical and disordered regions[24]. Because of differences in amino-acid composition and the effect of solvent conditions on the denatured form, some lack of correspondence between the optical rotation at a given wave-length ($[m']_\lambda$) and its change on denaturation ($\Delta[m']_\lambda^{H-D}$) with other rotatory dispersions parameters (λ_c, b_0 and a_0) may be expected[24]. However, the discrepancies in the case of the β-lactoglobulins are so unusual as to warrant further investigation. McKenzie *et al.*[25] have found values of $[m']_\lambda$ and $\Delta[m']^{H-D}$ signifying high helical content for the three bovine lactoglobulins. The change in a_0 found on denaturation indicates about a 70 per cent helical content. The native value of λ_c (245 mμ) only decreases by a small amount during urea denaturation and b_0 remains fairly constant at values indicative of a small helical content. Other workers have obtained similar results for β-lactoglobulin −*A B*. Since the β-lactoglobulins have a compact folded structure other chain arrangements must be considered to explain these unusual rotatory properties. Tanford *et al.*[27] explain the low b_0 as indicating a negligible helical content. However, Urnes and Doty[24] have made the alternative suggestion that the β-lactoglobulins have a mixed helical (60 per cent) and β-chain content. In this connexion it is of interest that the X-ray crystal investigations of Green *et al.*[28] indicate that the same proportion of the chain may be helically folded as in hæmoglobin.

McKenzie and Smith[14–16] have found that the absolute magnitude of the optical rotatory power of the cow β-lactoglobulins at *p*H 6·9 shows a slight increase with increasing temperature. At *p*H 2, where splitting into single chains is complete, there is also slight increase with temperature. At *p*H 9·1 there is an immediate increase in absolute magnitude of optical rotatory power compared with *p*H 6·9 at each temperature, but there is only slight increase of this value with increasing temperature. Although at *p*H 9·1 the lactoglobulins are denatured there must still be considerable constraints imposed (cf. the rule of Kauzmann and Eyring).

The other interesting optical rotatory properties are exhibited only by bovine β-lactoglobulin-*A*. At *p*H 4·7 the behaviour of β-*B* and β-*C* is similar to that at *p*H 6·9. On the other hand, in the temperature region where β-*A* associates to form tetramers (4 × 35,000) at *p*H 4·7 there is a considerable decrease in absolute magnitude of optical rotatory power with decreasing temperature. The optical rotatory dispersion parameters, thermodynamic data and the significance of these results will be discussed further elsewhere.

Sheep β-Lactoglobulins

We found that the boric acid–sodium hydroxide buffer of *p*H 8·5 used in the bovine lactoglobulin work and *tris* discontinuous buffers were unsatisfactory for demonstrating polymorphism of the sheep β-lactoglobulins by starch-gel electrophoresis[7]. However, a phosphate buffer of *p*H 7·6 and *I* 0·2 was found to be suitable. Examination of the Armstrong–McKenzie 'lactalbumin' fraction of milks of individual ewes showed that there are three main proteins in this fraction. These proteins have been identified as serum albumin, α-lactalbumin and β-lactoglobulin using as criteria of identification chemical, physical and immunological properties. This identification is in conflict with that of Darcel *et al.*[29] from filter-paper electrophoretic patterns. It can be seen from Fig. 2*a* that in the starch gel at *p*H 7·6 the order of mobility of these sheep proteins is serum albumin > lactalbumin > β-lactoglobulin. Serum albumin is not apparent in the electrophoretic pattern on paper of the concentrated 'lactalbumin' solution at *p*H 8·6, but the mobility of the β-lactoglobulin is greater than that of the α-lactalbumin. One-dimensional starch-gel electrophoresis at *p*H 7·6 of skim milks of individual ewes (73 Merino, 3 Romney Marsh, 35 Suffolk) showed the presence of two forms of β-lactoglobulin (Fig. 2*b*) of which either one or both (equal amounts) were present in all milks examined. These results suggested that the genes controlling production of the two types were alleles. A random sample of 62 Merino ewes from one flock were typed and the two-allele hypothesis tested. There was good agreement between the observed and expected numbers.

The faster-moving sheep β-lactoglobulin in starch gel at *p*H 7·6 has been designated β-*A* and the slower β-*B*. Both lactoglobulins have been isolated by the Armstrong–McKenzie procedure (Fig. 2*c*), but so far it has only been

possible to crystallize type *A*. The crystals resemble those of bovine β-*B* and β-*C*. It has been found by sedimentation investigations that sheep β-lactoglobulin-*A* does not associate at *p*H 4·7 and low temperature. Its sedimentation behaviour resembles that of bovine β-*B* and β-*C* and not bovine β-*A*. It is of interest that its aspartic acid residue content is similar to those of bovine β-*B* and β-*C*, affording further circumstantial evidence for the implication of the excess aspartic acid residues in bovine β-*A* being involved in the association at *p*H 4·7.

In collaboration with Dr. D. C. Shaw[21] we have found a general similarity between the amino-acid composition of the sheep and cow β-lactoglobulins, but there are differences which are sufficiently complex to preclude a simple comparison between species. The differences of sheep β-*A* compared with cow β-*B* (per 17,800 monomer) include: −1 lysine, −1 serine, −2 glutamic acid, +1 glycine, +1 valine, −3 leucine. The peptide maps of the two species have a gross similarity, but there are obvious differences.

Comparison of the amino-acid analyses of sheep β-*A* with sheep β-*B* indicates that *A* has −1 histidine and +1 tyrosine. Investigations in progress on the tryptic hydrolysates from performic acid oxidized material have shown that there is not a simple replacement of histidine for tyrosine. Two-dimensional electrophoresis (*p*H 1·9 and 4·7) resolved the extra histidine containing tryptic peptide in β-*B*, while the pattern from β-*A* had two other peptides. The amino-acid composition of one of these peptides from β-*A* is the same as the histidine peptide (containing 26 residues) from β-*B* except that it contains an extra glutamic acid or glutamine residue instead of histidine. The other peptide from β-*B* is not evident in the system used and so other means of separation are being explored.

Goat β-Lactoglobulins

The skim milks of 30 Saanen goats have been examined by starch-gel electrophoresis in the phosphate buffer (*p*H 7·6, *I* 0·2). Three bands were found in all the milks. It was shown by starch-gel electrophoresis at *p*H 7·6 and 8·5 of the 'lactalbumin' fraction, and of isolated β-lactoglobulin, that the slowest-moving band towards the anode under both conditions was β-lactoglobulin. No polymorphism of β-lactoglobulin was detected. This limited study does not exclude such polymorphism in goat milk, but it is of interest that Sen and Chaudhuri[30] were unable to detect any polymorphism by filter-paper electrophoresis investigations of 75 milks of individual goats from three Indian breeds.

Human β-Lactoglobulins

It has generally been considered that human milk contains β-lactoglobulin. Lunsford and Deutsch[31] demonstrated that serum albumin was present in human whey. Johansson[32] separated the whey proteins into three fractions: I, containing 55 per cent of the whey protein and similar in sedimentation behaviour to bovine α-lactalbumin (1·75 *S*); II, identical in electrophoretic and immunological behaviour to serum albumin; III, mainly a salmon-coloured protein (containing iron).

One of us (K. B.), in collaboration with Prof. O. E. Budtz-Olsen, has examined milks from 152 women (122 British, 6 Australian Aborigines, remainder various origins) by starch-gel electrophoresis at *p*H 8·5. The 'lactalbumin' fraction showed three bands, which were also exhibited in the skim milk patterns. The fastest-moving protein was present in the greatest amount and probably corresponds to the 1·7 *S* protein of Johansson. The second protein migrated at the same rate as serum albumin. The slowest protein had a very low mobility and possibly corresponds to fraction III of Johansson. On adjustment of the *p*H of the 'lactalbumin' fraction to 2, all three proteins were precipitated. Thus none of them corresponds in behaviour to the β-lactoglobulins of other species examined by us. No polymorphism was detected in any of the proteins. Further work on these proteins of human milk is in progress (K. B. and H. McK.).

Immunological Properties

Larson and Twarog[33] found that bovine β-lactoglobulins *A* and *B* were weak antigens compared with serum proteins and that they were immunologically identical. In the present work antisera against cow β-lactoglobulin-*AB* and β-lactoglobulin-*C* were produced in rabbits. The β-*AB* antiserum gave a single precipitin line with all three proteins with the Ouchterlony double-diffusion technique. On immunoelectrophoresis a single precipitin arc was obtained with β-*A*, *B* and with β-*C* against the β-*AB* antiserum. Similar results were obtained when the proteins were mixed two at a time (1 : 1) and subjected to immunoelectrophoresis. The experiments were repeated using β-*C* antiserum. All the results indicated that bovine β-*A*, β-*B* and β-*C* are immunologically identical.

Using similar methods it was found that sheep β-*A* and β-*B* are immunologically identical. Furthermore, the sheep β-lactoglobulins reacted strongly with complete cross-reaction with antiserum to the bovine proteins. Thus, either the antigenic portions of each of the bovine and sheep β-lactoglobulins are identical and the difference amino-acid residues are not involved in them, or the rabbit is incapable of detecting the differences between the two molecules and producing specific antiserum.

At the beginning of this article it was pointed out that the failure of many human mothers to breast-feed their babies has resulted in a number of problems arising in the use of milk substitutes. Many investigations have indicated that respiratory, dermal, gastrointestinal, anaphylactic and other reactions may result from allergy to cow milk[34]. Ratner *et al.*[35] considered β-lactoglobulin to be the dominant allergen in cow milk. Recent clinical and immunological studies cast some doubt on the validity of their conclusions[36]. Some workers have claimed allergic reactions in infants to human milk and/or to the milks of one or more of several ruminant species, β-lactoglobulin being implicated. The immunological identity of the ruminant β-lactoglobulins investigated in the present work and the failure to find similar β-lactoglobulin in human milk lead us to question the finding that β-lactoglobulin is the dominant allergen.

We thank Prof. O. E. Budtz-Olsen and A. G. Ogston for their interest and encouragement; the Australian Cattle and Beef Research Committee for a studentship (K. B.), the C.S.I.R.O. and the Australian Dairy Board for encouragement and financial assistance; and the Rural Veterinary Centre of the University of Sydney; the Herd Recording Section of the Queensland Department of Primary Industries and the Comptroller General of Queensland Prisons for access to their herds.

MECHANISM OF β-KETOADIPATE FORMATION BY BACTERIA

By L. N. ORNSTON and Prof. R. Y. STANIER
University of California, Berkeley, California

THE oxidative attack on many benzenoid substrates by bacteria leads to formation of either catechol or protocatechuate (3,4-dihydroxybenzoate) as the last intermediate possessing an aromatic structure (Fig. 1). These *o*-diphenols are substrates for oxygenative ring cleavage. Some bacteria attack them by oxygenation of the two adjacent carbon atoms which bear hydroxyl groups, to yield *cis, cis*-muconate and β-carboxy-*cis, cis*-muconate from catechol and protocatechuate, respectively. Both compounds are eventually converted to β-ketoadipate, which is in turn decomposed via acetyl-coenzyme *A* and succinate. This metabolic pathway is not confined to bacteria, since the mould *Neurospora crassa* can also convert protocatechuate to β-ketoadipate. Among bacteria, there are organisms that de-aromatize catechol and protocatechuic acid by a different oxygenative mechanism: only one atom of oxygen is added to a hydroxylated carbon atom, and a second is added to a neighbouring, non-hydroxylated carbon. The products of this mode of ring cleavage are α-hydroxysemialdehydes of the muconic acids, which are metabolized through pathways distinct from the β-ketoadipate pathway (Fig. 1)[1,2].

The general nature of these metabolic sequences has been known for some years, but the detailed biochemistry of the steps subsequent to ring cleavage has remained obscure. The purpose of this article is to describe the reactions which lead to the formation of β-ketoadipate from both catechol and protocatechuate, and to discuss their comparative biochemistry.

Formation of a muconic acid as the product of bacterial attack on catechol was first demonstrated by Hayaishi and Hashimoto[3]. The definitive characterization of this acid as the *cis, cis* isomer followed the elucidation of the chemistry of muconic acids and their lactones by Elvidge, Linstead *et al.*[4,5]. Evans and Smith[6] showed that only *cis, cis*-muconate can be converted to β-ketoadipate by extracts of benzoate-induced bacteria; and, in collaboration with Linstead and Elvidge[7], they showed that such extracts can also form β-ketoadipate from muconolactone (γ-carboxymethyl-Δ-α-butenolide, Fig. 2, structure III). The intermediacy of this lactone was confirmed by Sistrom and Stanier[8], who separated the enzymes of *Pseudomonas fluorescens* which convert *cis, cis*-muconate to β-ketoadipate into two fractions. One fraction catalysed the formation of (+)-muconolactone from *cis, cis*-muconate; the other converted (+)-muconolactone to β-ketoadipate. Evans *et al.*[7] suggested that another intermediate, γ-carboxymethyl-Δ-β-butenolide (Fig. 2, structure IV), might lie between (+)-muconolactone and β-ketoadipate, but without direct evidence for its occurrence.

The cleavage product formed from protocatechuate by *Pseudomonas fluorescens* was identified as β-carboxy-*cis, cis*-muconate by MacDonald, Stanier and Ingraham[9]. These workers found that only the *cis, cis* isomer of the tricarboxylic acid was converted to β-ketoadipate. We shall refer to the biologically active isomer as β-carboxymuconate. MacDonald *et al.*[9] chemically synthesized a carboxymuconolactone from β-carboxymuconate and found that this lactone was not attacked by extracts of protocatechuate-induced *Pseudomonas fluorescens*. Gross, Gafford and Tatum[10] established the structure of the

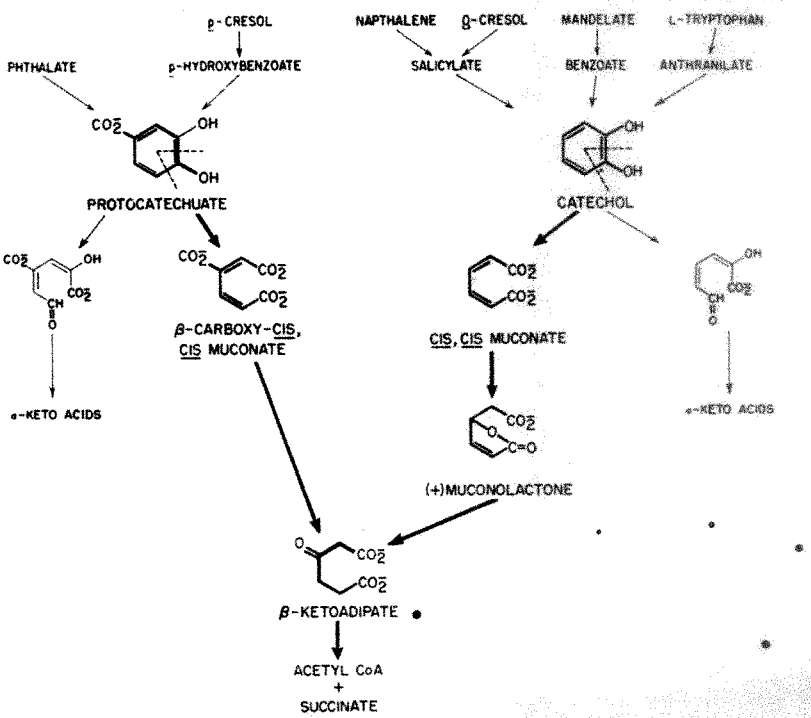

Fig. 1. A condensed metabolic map to show key positions occupied by catechol and protocatechuate in the bacterial degradation of aromatic compounds, and the divergent pathways for the breakdown of these diphenols

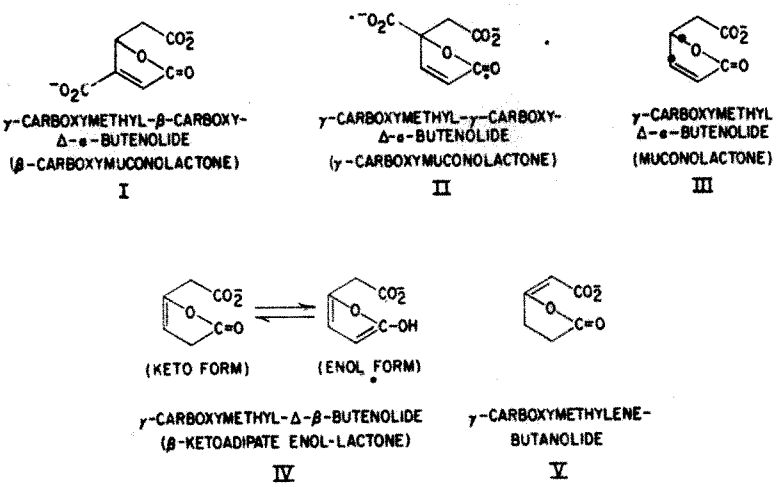

Fig. 2. Lactones related to the muconic acids. The names in brackets are the common names used in the text

chemically synthesized lactone as β-carboxymuconolactone (γ-carboxymethyl, β-carboxy-Δ-α-butenolide, Fig. 2, structure I) and showed that one of the optical isomers of this compound was an intermediate in the degradation of β-carboxymuconate by *Neurospora*. In contrast, Cain, Ribbons and Evans[11] found that β-carboxymuconolactone was not attacked by extracts of other protocatechuate-decomposing bacteria: *Nocardia erythropolis*, *Moraxella* sp. (*Vibrio* 01) (ref. 12) and a phthalate-utilizing pseudomonad.

Further evidence that the bacterial and fungal pathways diverge after ring cleavage was provided by the tracer experiments of Gross *et al.*[10], who analysed the labelling pattern in β-ketoadipate formed enzymatically from protocatechuate which had been specifically labelled with carbon-14 in the ring. The distribution of radioactivity in the β-ketoadipate formed by *Neurospora* extract was consistent with its formation via β-carboxymuconolactone, whereas the distribution in β-ketoadipate formed by an extract of *Pseudomonas fluorescens* was not, and seemed to indicate that the reaction proceeded through a symmetrical intermediate.

In reviewing this work, Elsden and Peel[13] suggested that the requirement for symmetry could be satisfied by 2,6-dioxa-3,7-diketo-bi*cyclo* (3,3,0) octane, the dilactone of *cis*, *cis*-muconate. However, both the dilactone and another possible symmetrical intermediate, β,γ-dihydroxyadipate, were afterwards excluded as intermediates by Cain, Ribbons and Evans[11], leaving the isotopic data of Gross *et al.*[10] without any satisfactory chemical explanation.

Far from clarifying the problem, subsequent work on the bacterial metabolism of protocatechuate introduced further complications. Cain and Cartwright[14] reported that an unidentified lactonic intermediate was produced in the conversion of β-carboxymuconate to β-ketoadipate by *Nocardia erythropolis*. Later observations by Cain[15] pointed to (+)-muconolactone (Fig. 2, structure III) as an intermediate in this conversion by *Moraxella* sp. He found that a heated extract of cells grown on *p*-hydroxybenzoate produced (+)-muconolactone from β-carboxymuconate, and that the unheated extract could convert this lactone to β-ketoadipate. Cain *et al.*[11] reported that extracts of *Nocardia erythropolis* and of a phthalate-utilizing pseudomonad could likewise convert (+)-muconolactone to β-ketoadipate, but confirmed the earlier observation of MacDonald *et al.*[9] that extracts from *p*-hydroxybenzoate-induced cells of *Pseudomonas fluorescens* cannot do so. These results implied that in addition to the distinctive *Neurospora* pathway, there are two distinct bacterial pathways for the conversion of β-carboxymuconate to β-ketoadipate: one characteristic of *Nocardia* and *Moraxella*, which passes through (+)-muconolactone, and one, characteristic of *Pseudomonas fluorescens*, which does not.

Our work was undertaken primarily to clarify the mechanism of β-ketoadipate formation from β-carboxymuconate by *Pseudomonas fluorescens*, which had been left completely obscure as a result of earlier investigations. During the course of a screening programme designed to obtain mutants of *P. fluorescens* strain *A*.3.12 with genetic blocks in the metabolism of benzoate, a considerable number of mutants which had lost simultaneously the ability to grow on benzoate and on *p*-hydroxybenzoate were isolated. The enzymes of the catechol pathway could be induced in these mutants by growth on asparagine in the presence of benzoate. Some of these mutants were clearly blocked below the level of β-ketoadipate; but extracts prepared from benzoate-induced cells of three of these mutants were unable to catalyse the formation of β-ketoadipate from precursors on the catechol pathway, indicating that the blocked step-reaction lay between (+)-muconolactone and β-ketoadipate (Fig. 1).

We shall refer to these particular strains as ELH⁻ mutants. Since (+)-muconolactone was known not to be an intermediate in the protocatechuate pathway in *P. fluorescens*, the inability of these mutants to grow on *p*-hydroxybenzoate indicated that the catechol and protocatechuate pathways must converge in an unknown intermediate immediately prior to β-ketoadipate, and that the affected step-reaction was the conversion of this common intermediate to β-ketoadipate. This inference was confirmed by the finding that an extract of wild-type cells grown on *p*-hydroxybenzoate, which cannot itself convert (+)-muconolactone to β-ketoadipate, can nevertheless confer this ability on extracts of benzoate-induced ELH⁻ mutant cells. By the use of (+)-muconolactone as a substrate in the presence of an excess of mutant extract, it became possible to measure in extracts of *p*-hydroxybenzoate-grown wild-type cells the activity of the enzyme responsible for the terminal step in the formation of β-ketoadipate. A typical experiment is illustrated in Fig. 3.

In principle, extracts of benzoate-induced ELH⁻ mutant cells should be able to accumulate the unknown

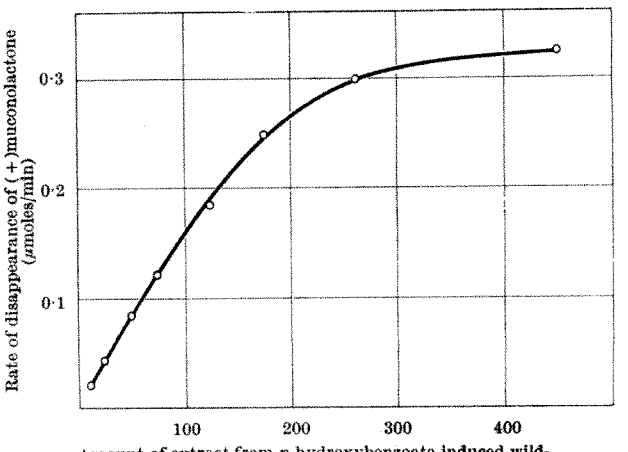

Fig. 3. Use of benzoate-induced ELH⁻ mutant for measurement of the activity of the enzyme which forms β-ketoadipate. Varying amounts of crude extract from *p*-hydroxybenzoate-induced wild-type cells were added to a series of cuvettes containing, in 3 ml., 100 μmoles *tris* (hydroxymethyl) aminomethane buffer, pH 8·0, 3 μmoles (+)-muconolactone and 250 γ-protein of extract from benzoate-induced cells of the ELH⁻ mutant. The reaction mixture was incubated at 25° C. Disappearance of the (+)-muconolactone was followed at 230 mμ

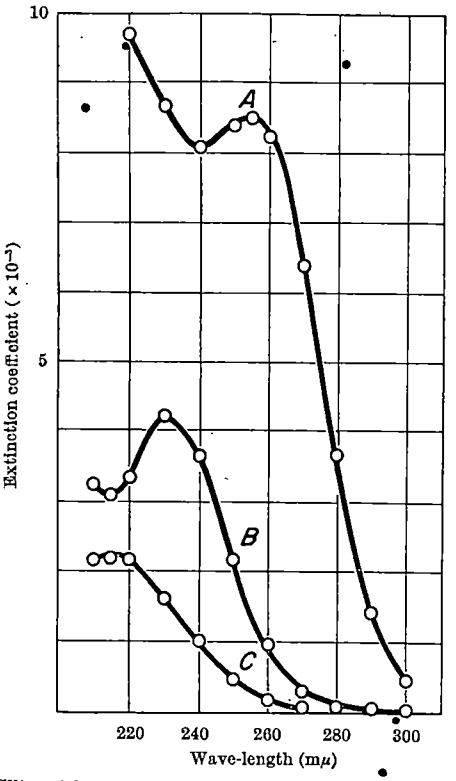

Fig. 4. Ultra-violet absorption spectra of intermediates between protocatechuate and β-ketoadipate, measured in aqueous solution at *p*H 8·0. Curve *A*, β-carboxymuconate; curve *B*, γ-carboxymuconolactone; curve *C*, β-ketoadipate enol-lactone

intermediate from precursors on the catechol pathway. However, proliminary examination showed that the principal compound which accumulates when such extracts are furnished with catechol or *cis, cis*-muconate is (+)-muconolactone, suggesting that the equilibrium between (+)-muconolactone and the unknown intermediate is strongly in favour of (+)-muconolactone. Accordingly, further attempts to prepare the intermediate enzymatically from precursors on the catechol pathway were abandoned in favour of an attempt to prepare it from precursors on the protocatechuate pathway. Since a decarboxylation occurs during the conversion of β-carboxymuconate to β-ketoadipate, it seemed reasonable to hope that the intermediate might arise in the protocatechuate pathway by an essentially irreversible reaction.

An extract was prepared from *p*-hydroxybenzoate-grown cells of the wild type, and the individual enzymes of the protocatechuate pathway were separated from one another and extensively purified by a combination of ammonium sulphate fractionation, heat treatment and column chromatography on DEAE cellulose and 'Sephadex *G*-100'. The problem was greatly facilitated by the existence of the indirect assay, described here, for the last enzyme of the sequence. The activities of the individual enzymes catalysing the successive steps between β-carboxymuconate and β-ketoadipate could each be measured spectrophotometrically, since β-ketoadipate is relatively transparent in the ultra-violet region, whereas β-carboxymuconate and the two intervening intermediates all show strong and characteristic ultra-violet absorption (Fig. 4). Purified enzymes were used for preparing these intermediates so that subsequent enzymes could be assayed.

The enzyme which attacks β-carboxymuconate is a lactonizing enzyme. One equivalent of acid per mole of substrate disappears on addition of the purified enzyme, and one equivalent of acid reappears on subsequent addition of crude extract, which converts the reaction product to β-ketoadipate. The product is a highly unstable carboxymuconolactone, probably identical with the lactone which Cain and Cartwright[14] reported to be produced by *Nocardia* extracts. It decarboxylates spontaneously to yield (+)-muconolactone (Fig. 5). We have not been able to isolate this intermediate; but the spectral properties, the lability of one carboxyl group, and the decomposition to (+)-muconolactone are compatible with only one structure, γ-carboxymuconolactone (γ-carboxymethyl-γ-carboxy-Δ-α-butenolide, Fig. 2, structure II).

The next enzyme in the sequence brings about the decarboxylation of this unstable lactone. As shown in

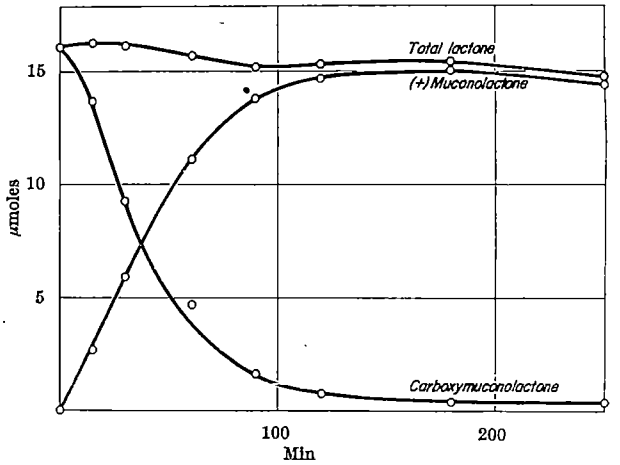

Fig. 5. Spontaneous decarboxylation of γ-carboxymuconolactone to (+)-muconolactone. The γ-carboxymuconolactone was generated enzymatically from β-carboxymuconate. Flasks contained, in 3 ml., 16·2 μmoles β-carboxymuconate, 200 μmoles sodium potassium phosphate and 20 μmoles citrate buffer at *p*H 6·0, and enough purified lactonizing enzyme to convert the β-carboxymuconate completely to γ-carboxymuconolactone in ten minutes. The reaction mixture was incubated at 30° C. Disappearance of γ-carboxymuconolactone and appearance of (+)-muconolactone were followed spectrally in aliquots of the reaction mixture

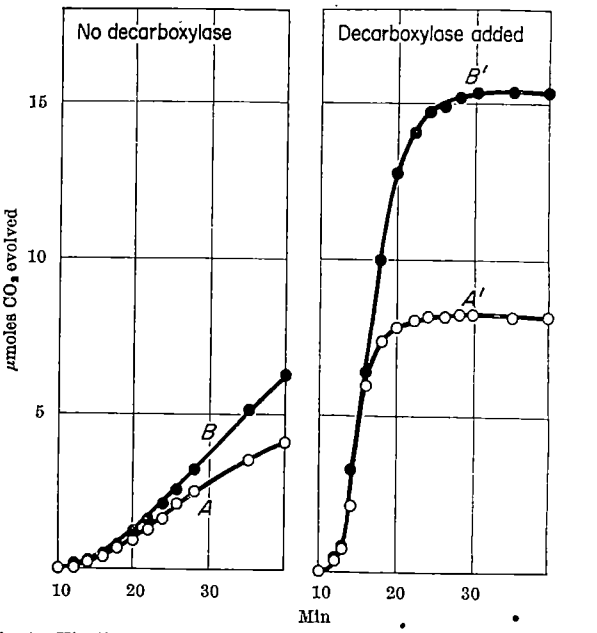

Fig. 6. Kinetics of the spontaneous and enzyme-catalysed decarboxylations of γ-carboxymuconolactone. The general conditions were the same as those for the experiment shown in Fig. 5. Flasks *A* and *A′* were furnished with 8·1 μmoles of β-carboxymuconate, flasks *B* and *B′* with 16·2 μmoles. All four flasks received at zero time an amount of purified lactonizing enzyme sufficient to lactonize the substrate at a rate of 2 μmoles/min. Flasks *A′* and *B′* received simultaneously an amount of purified decarboxylase sufficient to decompose γ-carboxymuconolactone at a rate of 5 μmoles/min. Accordingly, evolution of carbon dioxide in flasks *A* and *B* reflects the spontaneous decarboxylation of two different concentrations of γ-carboxymuconolactone, formed enzymatically from β-carboxymuconate; evolution of carbon dioxide in flasks *A′* and *B′* reflects the enzyme-catalysed decarboxylation of the same amounts of enzymatically-formed lactone

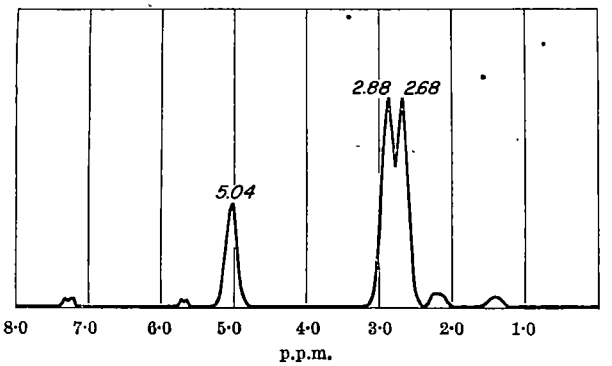

Fig. 7. Schematic magnetic resonance spectrum of β-ketoadipate enol-lactone in deuterated acetone. Values given for chemical shifts are in parts per million

Fig. 6, the addition of this enzyme to a reaction system containing β-carboxymuconate and the purified carboxymuconate lactonizing enzyme greatly increases the rate of production of carbon dioxide.

The product of the enzyme-catalysed decarboxylation of γ-carboxymuconolactone is also a lactone; a release of protons accompanies its conversion to β-ketoadipate. It is, however, clearly different from (+)-muconolactone, the product of spontaneous decarboxylation, since it can be converted to β-ketoadipate by crude extracts of *p*-hydroxybenzoate-induced wild-type cells. The new lactone was produced enzymatically from β-carboxymuconate and extracted from the acidified reaction mixture. The compound was crystallized (colourless needles, m.p. 72°–74° C) from a mixture of chloroform and *n*-hexane. Physical investigations indicated that this lactone was a structural isomer of muconolactone. The equivalent weight was 142, in agreement with the value for a monocarboxylic acid of the empirical formula $C_6H_6O_4$. Elemental analysis showed C, 50·02 per cent; H, 4·34 per cent; calculated values for $C_6H_6O_4$ are C, 50·71 per cent; H, 4·26 per cent. It was concluded that the new lactone was either γ-carboxymethyl-Δ-β-butenolide (Fig. 2, structure IV) or γ-carboxymethylenebutanolide (Fig. 2, structure V). Four lines of evidence indicate that the double bond is endocyclic, and hence that structure IV is the correct formulation. First, the spectrum of aqueous solutions of the lactone is identical at *p*H 8·0 and *p*H 2·0, which shows that the chromophore is independent of the carboxyl group. Secondly, its melting-point differs radically from the melting-point (176°–179° C) reported by Eisner, Elvidge and Linstead[16] for γ-carboxymethylenebutanolide. Thirdly, the nuclear magnetic resonance spectrum (Fig. 7) is consistent with structure IV, but not with structure V. The lactone dissolved in deuterated acetone exhibits in its proton nuclear magnetic resonance spectrum two protons at 2·68 p.p.m., two protons at 2·88 p.p.m. and one proton at 5·04 p.p.m. These chemical shifts correspond to two protons on the α-carbon, two protons on the Δ-carbon and one proton on the β-carbon, respectively, of γ-carboxymethyl-Δ-β-butenolide. Lastly, nuclear magnetic resonance investigations showed that the two protons on the α-carbon of the new lactone exchanged with deuterium ions when the compound was dissolved in deuterium oxide, indicating the occurrence of an equilibrium between the keto and enol forms as portrayed in Fig. 2, structure IV. The furan structure of the enol form no doubt explains the observed ultra-violet absorption of the compound in solution. We shall refer to this compound as β-ketoadipate enol-lactone.

When β-ketoadipate enol-lactone is added to a crude extract of benzoate-induced cells of the ELH⁻ mutant, it is almost completely converted to a mixture of (+)-muconolactone and *cis*, *cis*-muconate. This confirms the assumption, mentioned earlier, that the equilibrium between (+)-muconolactone and the subsequent intermediate in the catechol pathway is strongly in favour of (+)-muconolactone. At the same time, it demonstrates the position of β-ketoadipate enol-lactone as the first common intermediate in the catechol and protocatechuate pathways.

The enzyme responsible for the conversion of the enol-lactone to β-ketoadipate, enol-lactone hydrolase, has been extensively purified from cells of the wild type grown on *p*-hydroxybenzoate, but it occurs at comparable levels of activity in benzoate-grown cells. The purified enzyme, when added to crude extracts of benzoate-induced ELH⁻ mutant cells, permits a conversion of (+)-muconolactone to β-ketoadipate. Hence the genetic defect in these mutants, which prevents growth at the expense of both benzoate and *p*-hydroxybenzoate, is the inability to synthesize enol-lactone hydrolase.

The parallel pathways leading from catechol and protocatechuate to β-ketoadipate are shown in Fig. 8. In each sequence, there are three chemically homologous reactions which are, however, catalysed by two distinct series of enzymes, different both in substrate specificity and in inducibility. Convergence occurs with the formation of β-ketoadipate enol-lactone. Even though the formation of this lactone in the protocatechuate pathway involves

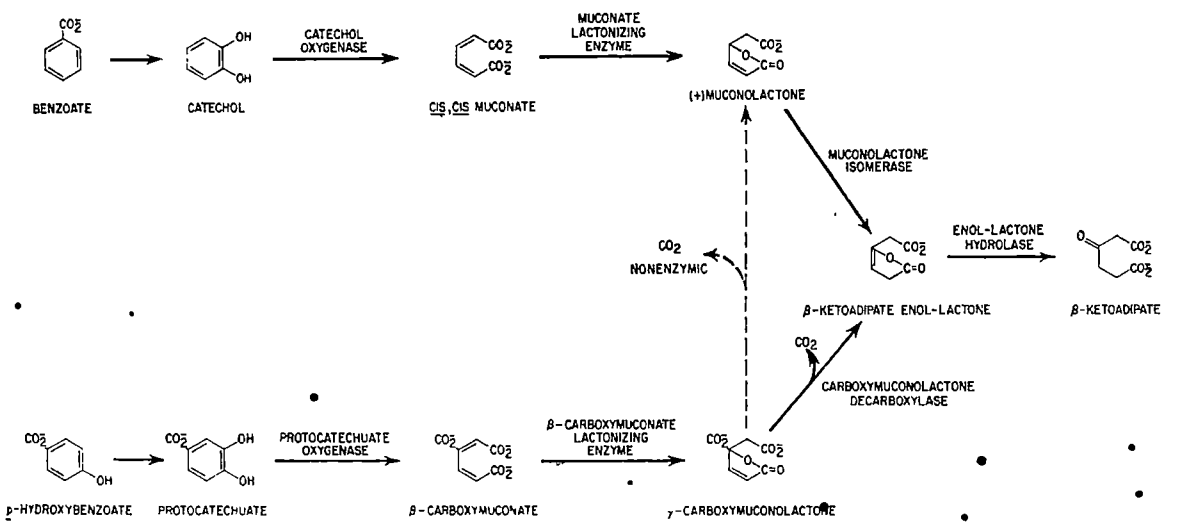

Fig. 8. The mechanism of β-ketoadipate formation by bacteria

a decarboxylation, the enzyme which catalyses this step is probably not a true decarboxylase; by analogy with the parallel step in the catechol pathway, its function is no doubt to catalyse the migration of the endocyclic double bond, decarboxylation being a necessary consequence of this structural change.

The pathway from protocatechuate to β-ketoadipate now established does not include a symmetrical intermediate, the existence of which was postulated by Gross, Gafford and Tatum[10] as a result of the finding that equilibration of a specific ring label initially present in protocatechuate occurs on its enzymatic conversion to β-ketoadipate by a crude extract of *P. fluorescens*. In fact, the only symmetrical intermediate in either the catechol or the protocatechuate pathway is *cis, cis*-muconate. Therefore, the only chemically plausible explanation of the findings of Gross *et al.*[10] is that the extract which they employed contained the enzymes necessary to catalyse a back-reaction which permitted an intermediate in the protocatechuate pathway (probably β-ketoadipate enol-lactone) to equilibrate with *cis, cis*-muconate.

The elucidation of the protocatechuate pathway in *P. fluorescens* has amply confirmed the surprising fact established by Gross *et al.*[10] that this bacterium and *Neurospora* convert carboxymuconate to β-ketoadipate by different biochemical mechanisms. We must now consider the evidence[14,15] which suggested the existence of an additional pathway for this conversion, passing through (+)-muconolactone, among bacteria. Since the evidence was obtained largely with *Moraxella* sp. ('*Vibrio* 01'), we have examined this organism, using the strain (NCIB 8250) used by previous workers[11,15]. Cain's allegation that heat-treated extracts of *p*-hydroxybenzoate-induced cells can form (+)-muconolactone from β-carboxymuconate is indeed correct; but this interpretation is not. Heating largely destroys carboxymuconolactone decarboxylase and completely destroys enol-lactone hydrolase. The γ-carboxymuconolactone which accumulates in the reaction mixture decomposes in part spontaneously to (+)-muconolactone, and in part enzymatically to β-ketoadipate enol-lactone. In the absence of enol-lactone hydrolase, the latter compound is back-converted enzymatically to (+)-muconolactone. The reported 'delactonization' of (+)-muconolactone to β-ketoadipate by unheated extracts of *p*-hydroxybenzoate-grown *Moraxella*[15] involves the action of two enzymes, muconolactone isomerase and enol-lactone hydrolase (Fig. 8). The former enzyme is, in *P. fluorescens*, specifically associated with the catechol pathway, whereas the latter is common to both the catechol and protocatechuate pathways. Hence the physiological significance of the 'delactonization' observed by Cain[15] depends on the level of specific activity of muconolactone isomerase in extracts of *Moraxella* grown on *p*-hydroxybenzoate. We have measured the level of this enzyme in extracts of *Moraxella* gathered during exponential growth at the expense of benzoate and of *p*-hydroxybenzoate. The specific activity of muconolactone isomerase in extracts of *p*-hydroxybenzoate-grown cells is clearly inadequate to account for the observed rate of conversion of β-carboxymuconate to β-ketoadipate, being forty times less than in benzoate-grown cells. Accordingly, none of the evidence which has been adduced to support the existence of a second pathway for this conversion in bacteria can be considered valid.

We thank Mr. George Hegeman and Miss Margaret Leroux, who isolated and generously furnished us with the ELH⁻ mutants. We also thank Prof. Rapoport and Mr. W. F. Benisek for their assistance in the determination and interpretation of nuclear magnetic resonance spectra.

The work was supported in part by a grant from the U.S. National Institutes of Health. One of us (L. N. O.) thanks the U.S. National Science Foundation for a pre-doctoral fellowship, during which this work was conducted.

TERMINAL DISTRIBUTION IN THE SUPERIOR COLLICULUS OF FIBRES ORIGINATING IN THE VISUAL CORTEX

By R. D. LUND
Department of Anatomy, University College, London

TOPOGRAPHICAL localization in the terminal distribution of fibres from the retina to the visual cortex and to the superior colliculus has been shown in a number of animals. Suggested interactions of these two end-stations of the visual input have been described by many workers on the basis of behavioural experiments; but the detailed anatomical organization of the pathways interconnecting them and the relationship of these pathways with the retinotectal and retino-geniculo-cortical tracts have not been considered.

No satisfactory evidence exists to demonstrate a pattern of localization in the termination of fibres arising in the visual cortex and ending in the superior colliculus. Evidence for restricted degeneration in the latter following partial lesions of the visual area is presented by Gerebtzoff and Wauters[1] for the rabbit and guinea-pig and by Nauta and Bucher[2] for the rat. Unfortunately both made too few lesions to allow a system of localization to be deduced. A further investigation of the problem by Crosby and Henderson[3] suggests a localization pattern, but their conclusions depend on inconclusive evidence.

The work recorded here was undertaken on the albino rat using the Nauta and Gygax method[4] to examine the pattern of degeneration in the superior colliculus following aspiration of areas within the visual cortex. To reduce subjective bias in assessing localization, sections were mounted randomly and serialized with reference to a Nissl-stained series after analysis. The lesion area was

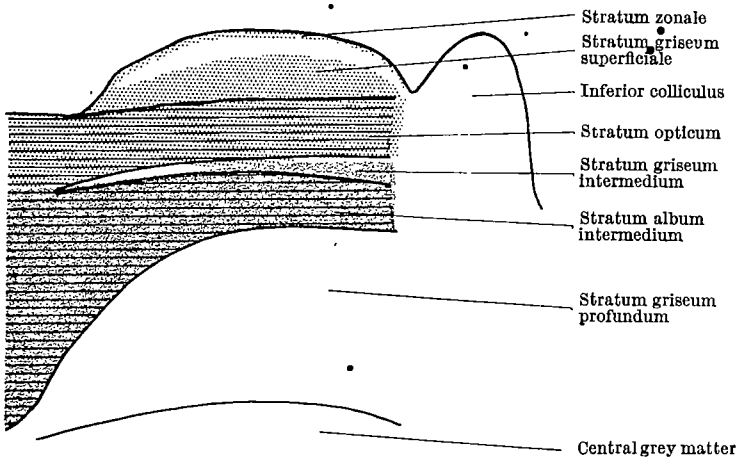

Fig. 1. Diagram of a parasagittal section through the superior colliculus of the rat. The lines indicate the afferent fibre laminæ, the dots show the area of degeneration following lesions of the visual cortex, and the stippling the degeneration after more rostral cortical lesions

mapped in relation to the posterior and medial borders of the cortex. In four brains with cortical lesions extending into the superficial part of layer IV or into layer III, no degeneration is seen in the thalamus, pretectum, or superior colliculus. As a result the area of the lesion was measured at the depth of layer IV when oblique sucker tracks were made or when lesions tapered from the surface inwards. Except for some of the large lesions which involve the superficial part of the underlying white matter, none extends deeper than layer VI.

The results summarized in Fig. 1 indicate that fibres from the visual cortex enter principally the stratum opticum of the colliculus and terminate in this lamina and the deeper part only of the stratum griseum superficiale. The density of degeneration is continuous from one lamina to the other. A few fibres run more deeply to terminate possibly in the most superficial part of the stratum griseum intermedium. However, since the boundary between this lamina and the stratum opticum is somewhat diffuse in the rat, it is not always clear within which layer this degeneration lies.

A small number of fibres run in the stratum zonale, a poorly developed layer in the rat, and evidence of termination can be seen here with the Nauta method. Degenerating fibres have never been seen passing from this layer to the subjacent stratum griseum superficiale. The paucity of fibres in the stratum zonale makes systematic localization impossible there. However, in the stratum opticum and the deeper part of the stratum griseum superficiale, there is good evidence of restricted degeneration following small lesions in the visual cortex, and the system of localization is the same in the two laminæ. The total area causing degeneration in these laminæ corresponds closely with the visual cortex defined by Lashley[5]. Ablation of the lateral part of this area causes preterminal degeneration in the rostral part of the superior colliculus, while damage to the medial part causes degeneration in the caudal part of the colliculus. Rostral lesions within the area cause medial degeneration and caudal lesions cause lateral degeneration. The area of degeneration relative to the total area of the stratum opticum is greater than is the area of the lesion relative to the total area of the visual cortex, even at the depth at which the lesion is most extensive. The effect of this apparent dispersion of fibres may be produced in part by spreading of the neighbouring cortex into the cavity of the lesion, so reducing its apparent extent. However, such expansion should be reflected in the packing density of the cells close to the lesion. This does not alter enough to account for the high ratio of degeneration area to lesion area.

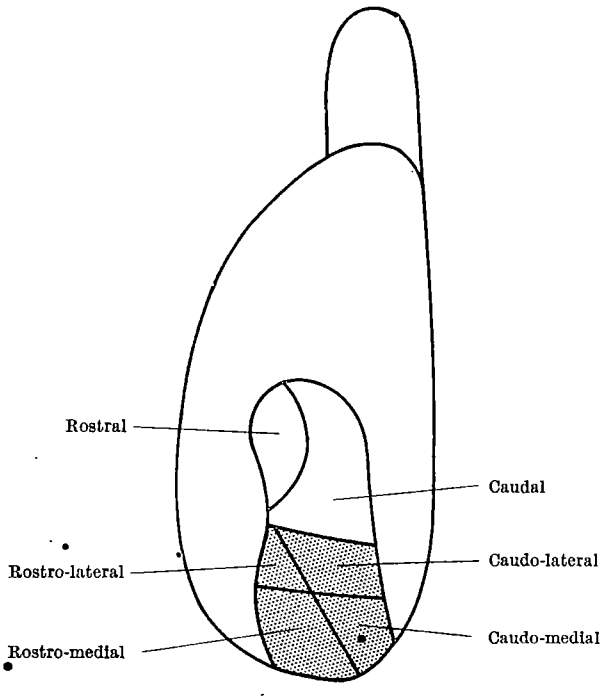

Fig. 2. Diagram of the left-hand cortex of the rat viewed from above showing the area that projects to the more superficial laminæ of the superior colliculus (stippled) and to the intermediate laminæ (clear area). The collicular receiving areas are indicated in relation to the areas of origin of corticotectal fibres

There is a relationship between this system of localization and that described by Lashley[6,7] for the retinotectal and retino-geniculo-cortical pathways of the rat. The area of cortex receiving fibres from the upper quadrant of the temporal retina of the contralateral eye projects to the area of the superior colliculus receiving retinotectal fibres from the same retinal quadrant. A similar situation is found with the other three retinal quadrants.

A further survey of degeneration produced in the superior colliculus has been made following lesions surrounding the cortical visual area to determine whether this area can be defined from neighbouring cortex in terms of its tectal projection. An area rostral to the visual area (Fig. 2) also projects to the colliculus. However, the fibres all enter by the stratum album intermedium and terminate in the posterior two-thirds of this lamina and of the stratum griseum intermedium. The preterminal distribution in the latter does not overlap that of fibres originating in the visual area. The passage and preterminal degeneration produced by rostral lesions is shown in Fig. 1. Localized degeneration is produced by small lesions; but there is considerable overlap of degeneration areas from lesions separated by several millimetres. There appears to be a pattern of localization as indicated in Fig. 2; but its significance is at present obscure. Lesions in the cingulate cortex, lying medial to the visual area, again produce no degeneration in the superficial laminæ, but some is found in the rostral part of the stratum album intermedium. Lesions in the auditory area, lying lateral to the visual cortex, show no evidence of degeneration in the superior colliculus.

From this work it appears that the superior colliculus of the rat may be divided into two sets of laminæ with regard to its afferent supply. One comprises the stratum opticum, griseum superficiale, and zonale, and possibly

part of the stratum griseum intermedium, and it receives fibres from the retina and visual cortex. The other comprises the rest of the stratum griseum intermedium and the stratum album intermedium, and receives fibres from cortical areas other than visual cortex, and from the spinal cord and other regions. How the individual inputs in each group are interrelated and what relation the two groups bear to one another are problems which are now under investigation.

I thank Prof. J. Z. Young for his advice. This work was carried out during the tenure of a University of London postgraduate scholarship.

SUCCINATE METABOLISM IN *Salmonella typhimurium*

Utilization of Succinate as Carbon and Energy Source by *Salmonella typhimurium*

SEVERAL mutants of *Salmonella typhimurium* were found to have a specific growth requirement for relatively high concentrations of aspartic acid when tested in the Davis–Mingioli medium[1] containing glucose, sodium citrate, and mineral salts. In the absence of glucose, however, the mutants grew readily without aspartic acid using citrate, fumarate, succinate, malate, or acetate as the sole carbon source. The results were similar to those reported by Gilvarg and Davis[2], in which a mutant requiring glutamic acid grew on citrate in the absence of glucose, the metabolic lesion being in the condensing enzyme which forms citrate. The growth of some of our mutants on the four carbon acids was repressed by glucose; others were not affected. Since the requirement in the present mutant was satisfied by 4-carbon as well as 6-carbon compounds, the results suggest that this strain lacked the ability to fix carbon dioxide via the reaction mediated by phosphoenol pyruvic carboxykinase, a condition previously described in a similar mutant[3]. In contrast, the wild-type parent *S. typhimurium* grew only very slowly with succinate, fumarate, malate or acetate as the sole carbon source; the mutant had gained the ability to utilize these organic acids in addition to losing the ability to grow with glucose. This paper presents some preliminary results which may explain this metabolic difference.

The *S. typhimurium* (wild type) used was a typical strain virulent for mice; the mutant (*X*39) was one of several auxotrophs isolated from the wild type after treatment with ultra-violet light[4]. The mutant grew with succinate either in the presence or absence of glucose but not with glucose alone. The basal medium, *p*H 7, contained (in per cent as w/v) 0·27 per cent $(NH_4)_2SO_4$, 0·5 per cent K_2HPO_4, 0·01 per cent of a solution of trace minerals which consisted of 10 per cent $MgSO_4$, 1 per cent $MnSO_4$, 0·1 per cent $FeSO_4$ and 3 per cent HCl. The carbon source was added in the amount of 0·2 per cent, and for investigations using solid media 0·85 per cent 'Ion Agar No. 2' (Oxoid) was included. Inocula were grown in the basal medium containing glucose and L-aspartic acid as the carbon source. Broth cultures were incubated in 250-ml. flasks on a rotary shaker at 37° C. The optical density was measured at 425 mμ; respiration studies were made using the Warburg respirometer with air as the gas phase.

Both the mutant, *X*39, and the wild type respired succinate at approximately the same rate; neither strain respired citrate, although both could utilize it as a growth substrate. This was in keeping with the findings of other workers that bacterial cells are impermeable to citrate unless a specific permease has been induced. The inability of the wild type to grow rapidly on succinate as the sole carbon source could not be ascribed to the impermeability of the cells to succinate.

The ability of both strains to grow readily on citrate as the sole carbon source suggested that the tricarboxylic acid cycle was functional in both organisms. A number of supplementary compounds were added to the succinate minimal medium to determine if any would enhance growth. Of the compounds tested, acetate, pyruvate and glutamate stimulated the growth of the wild strain, acetate being most effective. Rapid growth occurred only on the combination; the organism grew slowly on acetate alone (Table 1).

Table 1. GROWTH RESPONSE OF THE WILD-TYPE *Salmonella typhimurium* TO SUCCINATE AND ACETATE

Addition to basal medium (%)		*O.D.** after 9 h
Sodium succinate	0·2	0·03
Sodium acetate	0·1	0·06
Sodium succinate	0·2	0·47
+sodium acetate	0·06	
Sodium succinate	0·2	0·80
+sodium acetate	0·1	

* Measured at 425 mμ.
Note: a comparable culture of the mutant *X*39 reached an *O.D.* of 0·80 in a similar period of time in the medium containing 0·2 per cent sodium succinate.

These results suggested that the wild-type *S. typhimurium*, when grown on succinate, lacked sufficient endogenously formed acetate to permit rapid growth. Pyruvate was considered a precursor to acetate. Since both strains oxidized succinate at about the same rate, and to about the same extent, it seems unlikely that acetate functioned solely as a precursor in the essential formation of citrate in the growing culture. The economy of acetate in the wild type may have been such that the rate of those biosynthetic pathways dependent on acetate became limiting.

Finally, on occasions, rapidly growing strains of the wild type (prototrophs) were obtained which behaved on succinate media as did mutant *X*39 except that they also grew on glucose as the sole carbon source. This observation confirmed our belief that gaining the ability to utilize succinate for growth was independent of the ability to utilize glucose. Studies are being continued in hopes of clarifying the metabolic distinction between these strains.

Succinate Metabolism and Virulence in *Salmonella typhimurium*

Two kinds of strains of *Salmonella typhimurium* which can be distinguished by their behaviour on succinate as sole carbon source have been described in the preceding communication. One kind grows rapidly, yielding colonies

Table 1. Virulence of *Suc-E* and *Suc-L* metabolic types of *Salmonella typhimurium* administered intraperitoneally in albino mice

Dose	Dead/total (21 days)		Days to achieve 50% mortality	
	Suc-L	*Suc-E*	*Suc-L*	*Suc-E*
10^2	0/6	0/6	—	—
10^3	2/6	1/6	—	—
10^4	4/6	4/6	10	17
10^5	6/6	4/6	7	12
5×10^5	6/6	6/6	4	10
10^6	6/6	6/6	3·5	6
LD_{50}	4×10^3	8×10^3	—	—

* Calculated by the method of Reed and Muench[2].

visible at 24 h (designated *Suc-E*), and the other grows slowly, requiring 48 h for colonies to appear (designated *Suc-L*). This behaviour is also apparent in liquid medium in which *Suc-E* reaches maximal growth in 24 h while comparable inocula of *Suc-L* require 52 h to reach the same crop. Both were prototrophic strains derived from the same culture (strain wild 7, described by Herzberg[1]). Both strains grew well on glucose as sole carbon source, were antigenically smooth, were of equal endotoxicity, and both remained stable on sub-culture. The LD_{50} values, of the two strains, determined intraperitoneally in albino mice, were not significantly different and we would have assumed that the two strains did not differ in virulence. However, an examination of the time required for equivalent doses to kill showed that the TD_{50} values (days required for 50 per cent mortality) were consistently greater for the *Suc-E* strain (Table 1). Organisms were cultured from liver and spleen of animals infected with each strain and were tested for time required to yield visible colonies on succinate medium. The *Suc-L*-infected mice yielded only *Suc-L* organisms during a 12-day observation period. The bacterial population in animals infected with *Suc-E* changed from no detectable *Suc-L* in the inoculum administered to the animals to 40 per cent *Suc-L* by the 2nd day, 80 per cent by the 4th day and 100 per cent *Suc-L* by the 8th day of infection. Thus, the organisms which ultimately killed the mice were not the *Suc-E* strain inoculated, but rather *Suc-L* which had emerged from the *Suc-E* population *in vivo*. The delay in kill by the *Suc-E* infection was presumably due to the time required for the *Suc-L* population to grow out while the original *Suc-E* population diminished in numbers, and eventually was cleared by the animals. This pattern of a 'change-over' in population *in vivo* was consistently reproducible in a number of independent experiments. The phenomenon demonstrates the *in-vivo* selection of a metabolic type of *S. typhimurium* by animal passage, a procedure known to enhance virulence[3]. Whether this phenomenon is due to selection of *Suc-L* mutants present in the original population of *Suc-E* inoculated or to a 'mutagenic' or 'converting' mechanism present in the susceptible animals is at present under investigation. We can offer no hypothesis at this time for the correlation of virulence and succinate metabolism in this host-parasite interaction; we have found the correlation in a number of strains of *S. typhimurium* of independent origin. We believe that this is the first instance reported which links a metabolic phenomenon with virulence in this species.

SOIL FERTILITY PROBLEM IN ARID AND SEMI-ARID LANDS

By Dr FRITZ PAULI
Research Branch, Canada Department of Agriculture, La Pocatière, Quebec, Canada

THE population of the world, at the moment, is more than 2,700 millions. This figure will be doubled during the next fifty years if the present rate of growth continues. The majority of all human beings are very anxious to improve their living standard and want eagerly to reach the level of living which at present is enjoyed by only a privileged minority.

These two facts, namely the rapidly increasing pressure of population and the demand for high-quality foodstuffs, lead to the necessity of developing and making use of lands which until now have been overlooked. These regions were not taken into consideration so long as more favourable conditions could be found somewhere else. The vast soil resources of the sub-polar regions, of the humic tropical zones, and of the arid and semi-arid lands are potential agricultural *lebensraum*. The last group especially is of great importance, as more than one-third of the total continental globe suffers under these climatic conditions. It is worth knowing that only one-tenth of the continental surface is under agricultural cultivation.

Furthermore, the majority of the young developing nations, for which the quick development of all natural nutritional resources is decisive for their existence and future, are situated in the arid and semi-arid climatic belt. The problems connected with the agricultural use of these vast stretches of virgin lands are manifold and are of a very intricate nature.

The number of investigations of the agricultural prospects of soils in arid and semi-arid regions are growing steadily, but only a few are concerned with the practical use of these lands. Most of the investigations deal with hydrology in these zones and touch very briefly the importance of soils under the prevailing climatic conditions.

Measures for utilizing and improving arid and semi-arid soils, and for growing various crops, can be designed only after applying the general principles of soil and crop science to the specific conditions. This article deals only with the soil aspect.

Climate and Soil

Since the atmosphere is resting on the biosphere, air temperature, soil temperature, dew point, solar radiation, and moisture are important for the energy exchange in the biosphere. Sunlight, thermal radiation, evaporation, convection, and conduction all interact with the soil surface. They deliver a net energy to the soil or abstract energy from it. To understand the energy budget at the surface of the Earth the net radiation has to be known,

which is the difference between all downward streams of radiation and all upward streams of radiation, and is expressed in kg cal/cm²/year.

During a normal year, the atmosphere above arid and semi-arid lands takes up much more water evaporating from the soil surface and transpired by the plants than the amount of water which reaches the soil as precipitation. There is a negative balance between the yearly precipitation and the evapo-transpiration.

In the arid regions with low and sporadic rainfalls a thin soil-layer is formed which, by low leaching, is fairly rich in mineral plant nutrients. The lack of a continuous and closed vegetational cover prevents the formation of a thicker soil mantle. Organic residues, normally given off to the soil by the plant-root system, do not accumulate. Therefore, in the strict sense of the science of the soil, in most arid regions there are not soils, because the mineral component with the organic substances, together with the soil organisms do not form an inseparable entity.

On the contrary, in the semi-arid regions with their distinct summer or winter rainfall seasons, soil formation occurs. The more developed vegetational cover (typical steppe grasses) even leads to the meagre formation of humic compounds, giving these soils a slightly darker colour.

Apart from the deficiency in rainfall, the most characteristic factor of soil formation in arid and semi-arid regions is the dynamics of the weathering processes, the nature of which is primarily a physical one with slight chemical reactions. There is almost complete disintegration of the primary soil minerals, formation of secondary clay minerals of the kaolinite type, and accumulation of iron oxides and, sometimes, alumina. There is a very slight horizon differentiation, having a uniform distribution of the various fractions throughout the profile, sand (0·2–2·0 mm diameter per grain) being the most prominent part of it.

Unfortunately, the adsorption capacity of kaolinite for plant nutrients is rather low. Rapid leaching by torrential rainstorms in the semi-arid regions during the rainy season causes a severe deficiency in bases, making the soil complex especially poor in trace elements. The prevalence of free iron oxides in the mineral colloids of the soil produces a stable microstructure and makes for high porosity and water permeability.

These structural qualities of arid and semi-arid soils are very suitable for plant growth; but they should be considered when irrigation projects are planned.

Humic Compounds and Soil Fertility

The soil differs from its mineral parent material by its fertility as an indestructible and permanent property. In the formation of soil fertility, the organic substances reaching the soil as plant residues and animal remains, which are transformed by microbial activity into humic compounds, play the decisive part. These newly synthesized, dark brown, organic colloids have a beneficial effect on the physical, chemical and biological properties of the soil. They contribute prominently to the formation of a permanent and stable structure (crumby structure) of the soil which, on the other hand, has a favourable influence on the water-retention and heat turn-over of the soil. In addition to this is their importance for the nutrient supply of the higher plant. In the first instance, humic compounds possess a very high adsorption capacity which surpasses that of kaolinite by at least 50–80 times and is even considerably higher than that of the most active clay mineral, namely montmorillonite. Moreover, the main part of the total nitrogen in the soil occurs in the organic form (more than 85 per cent) of which the greatest part is aliphatically and heterocyclically incorporated into the humic compounds. For soil formation processes the chelating and complexing properties of the humic colloids are of primary importance.

Almost all the available phosphorus in arid and semi-arid soils is a product of biological accumulation, which prevents it from being fixed by the iron and alumina ions of the mineral colloids. There exists a mutual peptization effect between humic compounds and phosphorus complexes. This fact alone emphasizes once again the acuteness of the humus problem in arid and semi-arid soils, where phosphorus is the scarcest element of plant nutrition.

Very recently, the direct influence of the humic substances as highly active polymers with quinonoid character on the growth and the development of the higher plant has been established. During these processes in which humic compounds act as additional enzyme systems the osmotic value of the plant cells is increased, the transpiration considerably lowered, and therefore the wilting resistance strengthened. These results of modern humus research during the past two decades are of significant importance for the solution of soil fertility problems and practical agriculture in the regions which have still to be developed.

Humus Formation

The total reaction complex of the transformation of all plant residues and animal remains in the soil into humic compounds depends on the activity of all micro-organisms present in such a soil. They perform and exercise numerous biochemical functions, and the soil may be regarded as a tremendous biochemical laboratory.

The accumulation of humus in a given soil is not dependent only on the absolute amount of the total organic rests returned to it but depends to a certain extent also on the decomposability of these starting materials.

In one pathway of processes, the micro-organisms incorporate all organic material as energy sources into new biological processes, catabolizing them completely to carbon dioxide and water. This process normally is known as 'mineralization'. Under certain, more unfavourable environmental conditions, the plant cell-wall structures and animal tissues are broken down by micro-organisms only to specific building blocks. These low-molecular precursors of humic substances by condensation and polymerization yield high-molecular humic compounds, a process normally known as 'humification'. Mineralization and humification, therefore, are to a certain extent synonymous in their character, namely, energy-yielding pathways. Only in the second phase of humification, contrary to mineralization, does a synthesis of organic colloids take place which is mainly physico-chemical in its character.

The intensity of microbial action is in a great measure dependent on the hydro-thermic conditions which prevail in the upper crust of the Earth (0–15 cm as the most important horizon). Temperature increases up to 30° C stimulate the biochemical activity of the soil organisms, but this activity drops sharply after passing this optimum. Even numerous micro-organisms become active in the soil when the moisture content is rather low (*p*F values of about 4·0); they show full activity only when the soil reaches 40–60 per cent of its water-holding capacity (*p*F values of about 3·0). Simultaneous increase of both temperature and moisture above the optimal values (but also the decrease of both factors) delays the decomposition of the organic rests. As in any other biological activity, the decomposition rate is governed by the factor in minimum.

Generally, it can be said that the more favourable the environmental conditions (temperature, moisture, and aeration) the lower are the chances for the forming of humic compounds, since micro-organisms, as all biological entities, are inclined to break down energy sources indiscriminately and completely so long as starting material is available.

Apart from the importance of temperature and moisture conditions for the transformation of organic remains in the soil, the quality of the newly synthesized humic compounds, their particle weight and the number and kind of their exhibited active groups depend very much on these parameters. Consequently, the organic colloids in the soils of different climatic regions are very varied, not only quantitatively but also in their physicochemical character.

Breakdown of Humus

Humic compounds are not of a constant and permanent nature. They undergo continuous changes, multiplications as well as diminutions. Representing a dynamic system, they depend for their parent material, the organic rests, on a number of different factors. Fluctuations of the climate in the biosphere, soil biological activity, and activity of man during soil cultivation (seed-bed preparation) are the ruling parameters inseparably and intimately connected and influencing each other.

The humic colloids may be regarded as three-dimensionally cross-linked, predominantly aromatic systems. Apart from covalent bonds in their micro-building units, there are hydrogen bonds active in the cross-linking of 'monone' to 'polyone', and further to micelles. Such bridges exist between neighbouring phenolic and hydroxyl groups in the humic sphero-colloids. The presence of 'inner' and 'outer' hydrogen bonds leads to humic acid associations of coacervate structure, depending on their concentration in a medium and on the nature thereof. With decreasing particle concentration in humus soils a splitting-up of the micelles into 'polyone' occurs, accompanied by a decrease in viscosity.

Even though humic compounds by their aromatic nature are very resistant to microbial degradation they undergo fundamental changes with time. Pseudomonaceae, Myxobacteria, Proactinomycetes, Actinomycetes, *Penicillia*, and Basidiomycetes possess the necessary enzyme systems to use these complex substances as energy sources. Nitrogen-containing humic compounds especially are catabolized, the aliphatic and heterocyclic nitrogen being released by the breaking-up of the ring structures. But, in general, these organisms must be stimulated by certain environmental conditions before they attack the humus. The addition of small gifts of fresh plant residues to the soil is accomplished normally by a breakdown of the dark brown, colloidal substances. Moreover, during the numerous soil mechanization measurements for the preparation of the seedbed in order to cultivate the higher plants, a rapid loss of accumulated soil humus under a permanent vegetational cover (virgin or planted grassland) can be observed. Both treatments, incorporation of fresh plant rests and mechanical treatment of the soil, lead to a strong increase of biological activity in the soil. The microbial enzyme systems involved in the humus turn-over are polyphenoloxidases. During favourable oxygen tension and facilitated gas exchange, these oxidation enzymes become strongly activated. Every soil treatment, leading to the exposure of fresh soil surface, carries in itself the stimulation of biological activity and, therefore, is of acute danger to the maintenance of humus in the upper crust of the soil.

This is especially true for the light sandy soils in the arid and semi-arid regions which, by their high porosity (43·5 per cent of pore space), have already under normal circumstances a favourable gas exchange and therefore a limited humus content. These soils react especially sensitively on further exposure brought about by cultivation methods with modern machinery and implements.

But there arises another limiting factor for the maintenance and preservation of humus in soils of arid and semi-arid lands. During the summer or winter rainfall seasons these soils undergo a continuous drying and re-wetting, similar to the conditions of irrigated soils in such climatic belts. After strong, sporadic, and localized downpours the soils dry off very quickly, especially in the upper crust which contains the main part of the root system of the higher plant. During this process of drying, humic compounds are set free which previously were strongly adsorbed on soil minerals, especially on clay colloidal material These clay-humus complexes are very resistant to microbial attack. It seems that, during drying of the soil surface and its exposure to the solar radiation, photochemical processes are taking place. In these reactions water-soluble humic substances are re-formed from already highly polymerized humus and micro-organisms find them a suitable energy-source.

It must be remembered that the solar energy flux in most arid and semi-arid regions (North American desert zones, South American pampas, African dry lands, Asian continental steppes, and Australian scrublands) is fairly constant throughout the year. During daytime, very intense sunlight reaches the surface of the soil in these vast stretches of hostile land mainly undisturbed by clouds (about 9 h daily sunshine as annual long-term average). Also, the clearer skies above these lands cause much stronger nocturnal cooling at the soil surface, the clear and dry atmosphere allows almost full penetration of solar radiation, ranging from about 200 mμ to 23μ with energy peaks just beyond 1,000 mμ or 1μ. Twenty-nine per cent of the irradiated energy lies at wave-lengths greater than 1μ, and 50 per cent lies beyond the red of the visible spectrum.

By exposure to such radiation, especially in the range between 200 and 800 mμ, reactions of many types of synthesis and decomposition, polymerizations and dissociations, as well as oxidations and reductions, can be brought about. Hydrogen bonds and other short-range inter-molecular forces are most vulnerable to irradiation, and an unlimited number of degradation products may appear from large organic molecules during such reactions. In secondary processes, the building blocks of the complex molecules may again react with each other to form new compounds.

Consequently, in the very delicate process of humus dynamics, prominently occurring in the upper crust of soil, one cannot separate the biological world from the physico-chemical phenomena. The application of the newest results of 'phototropy' and 'photosensitized reactions' to soil fertility problems in arid and semi-arid regions—via humus research—is long overdue.

It is now essential that such basic investigations be started and properly integrated with hydrological investigations and planning in these climatic zones.

The agricultural usage of dry lands, predominant in the developing countries, is the greatest challenge to our knowledge in soil fertility. Only with great precaution and skill can complex cultivation methods be applied to such soils which by their peculiar nature are very sensitive to wind and water erosion. Sound knowledge of the two fundamentals of agriculture in arid and semi-arid zones—water and humus—is necessary if disappointing set-backs are to be avoided, causing not only large financial losses but in most cases forfeiting irretrievably the confidence of the farmers involved.

Nations with a long and successful agricultural tradition, planning the improvement of agricultural practices in order to make use of lands in arid and semi-arid zones, are well advised to start long-term research work on microclimatology, hydrology, and biochemistry of the soil. New methods of agricultural management, including the increased use of organo-mineral fertilizers (ammonized lignites) and of industrial waste-products (processed sulphite liquors) as prominent sources of high-quality humic compounds, will undoubtedly yield much new and surprising information and result in efficient agricultural usage of these critical but promising lands.

GEOPHYSICS

Estimation of Half-lives from Meteoritic Data

MOST investigations of cosmic ray nuclear interaction effects in meteorites have been aimed at deducing information on the history of cosmic radiation or on the history of the irradiated solid material[1]. It is the purpose of this communication, in part, to use such investigations for the determination of an approximate half-life.

The case illustrated is that for ^{44}Ti, recently found to be 48·2 ± 0·9 years[2]. The results obtained from meteoritic data are within 25 per cent of this value, while results based on cross-section arguments have been in error by as much as a factor of 20. Experiments of a similar nature are planned to estimate the ^{32}Si half-life.

The first ^{44}Ti half-life estimate, ⩾23 years, was given by Sharp and Diamond[3]. This estimate was later revised upward to 1,000 years[4] and then to ~200 years[1]. Until very recently, however, no direct measurement had been made.

In principle it should be possible to measure the half-life of ^{44}Ti by determining its production rate in a meteorite with an appropriate terrestrial age, t, and comparing the observed ^{44}Ti activity, A, with the theoretical value, A_0. The decay constant, λ, can then be calculated by means of the well-known formula:

$$\frac{A}{A_0} = e^{-\lambda t} \qquad (1)$$

The production rate, however, is a function of the cosmic ray intensity- and energy-spectrum which, in turn, is dependent on the degree of shielding which the meteorite had while in space. For all meteorites studied thus far, the theoretical production rate is so uncertain that such a treatment is not feasible.

Another approach is possible, however. If the ratios of the concentrations of a number of cosmogenic nuclides can be obtained between two meteorites of known terrestrial ages, t_1 and t_2, a theoretical ^{44}Ti ratio, R_0, can be calculated which is already corrected for shielding effects. The observed ratio, R, can then be related to the decay constant, λ, by:

$$\frac{R}{R_0} = e^{-\lambda (t_2 - t_1)} \qquad (2)$$

As it happens, an appropriate pair of iron meteorites is Treysa (fell April 3, 1916) and Aroos (fell November 24, 1959). Table 1 lists those nuclides which have been measured in both meteorites. The stable nuclide ratios have been corrected for the different cosmic ray exposure ages (Aroos, 980 m.yr.; Treysa, 530 m.yr.) of the two meteorites[5]. The uncertainties in these corrections have been included.

Table 1. COSMOGENIC NUCLIDES IN THE AROOS AND TREYSA IRON METEORITES

All stable isotope ratios have been multiplied by a factor of 1·85 to correct for the different exposure ages of these meteorites (ref. 5)

Nuclide (half-life)	Units	Aroos (ref.)	Treysa (ref.)	Treysa/Aroos
^{21}Ne	10^{-8}scc/g	8·20 ±0·10 (5)	8·00 ±0·25 (5)	1·81±0·38
^{26}Al (7·4 ×10^{5}y)	dpm/kg	1·47 ±0·15 (5)	2·69 ±0·34 (5)	1·83±0·30
^{36}Cl (3·1 ×10^{5}y)	dpm/kg	14·0 ±1·4 (8)	22·0 ±2·0 (1)	1·57±0·21
^{38}Ar	10^{-8}scc/g	42·0 ±2·2 (5)	32·4 ±1·3 (5)	1·43±0·31
^{45}Ca	ppb	1·7 ±0·15 (7)	1·15 ±0·06 (7)	1·25±0·29
^{44}Ti (?)	dpm/kg	2·40 ±0·30 (5)	1·23±0·59 (5)	0·51±0·25
^{46}Ca	ppb	0·039±0·004 (7)	0·030±0·002 (7)	1·42±0·34
^{50}V	ppb	4·79 ±0·40 (7)	2·47 ±0·20 (7)	0·96±0·23

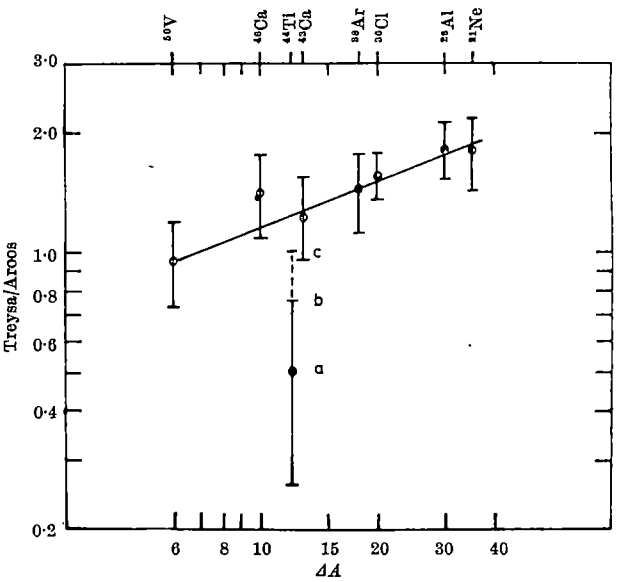

Fig. 1. Treysa/Aroos cosmogenic nuclide ratios versus ΔA, the difference in mass between ^{56}Fe and product nucleus. From these data the most probable value for the ^{44}Ti half-life is $36^{+\infty}_{-19}$ years. ○, stable nuclides; ●, radioactive nuclides

Fig. 1 shows the values of these ratios plotted versus ΔA, the difference in mass between the principal target nucleus (^{56}Fe) and the measured nuclide. Although many of these nuclides are non-cumulative, their position along a straight line indicates that the ratio of the spallation yields of the isobars may be assumed to be constant for the two meteorites. For a ΔA of 12, that is, ^{44}Ti, the production ratio between Treysa and Aroos should be 1·24. The observed value is considerably lower, 0·51 ± 0·25, and this 'depletion' may reasonably be ascribed to terrestrial decay.

The three points, *a*, *b* and *c*, which are indicated in Fig. 1 correspond to the most probable value, the 1σ limit (67 per cent confidence level), and the 2σ limit (96 per cent confidence level). The half-lives corresponding to these points are listed in Table 2. From these values it may be seen that the ^{44}Ti half-life almost certainly is less than 160 years, and its most probable value is about 36 years.

Table 2. COMPARISON BETWEEN THE ^{44}Ti HALF-LIFE CALCULATED FROM COSMOGENIC NUCLIDES AND THE MEASURED VALUE

Value	Half-life (years)
Most probable	36
67% confidence level	⩽65
96% confidence level	⩽160
Measured value (ref. 2)	48·2±0·9

Comparison with the actual ^{44}Ti half-life, 48·2 ± 0·9 years, indicates that the meteoritic technique seems potentially more accurate than cross-section arguments for such estimations.

A similar investigation for estimating the ^{32}Si half-life, now supposed to be about 500 years[6], requires a meteorite which fell before about 1650. Likely candidates are Elbogen (fell 1400) and Jalandhar (fell 1621).

In addition to allowing an estimate of the ^{44}Ti half-life to be made, several other facts can be deduced from Fig. 1. First, the meteorites, Treysa and Aroos, suffered either equal or no space erosion during at least their last few hundred thousand years of cosmic ray irradiation[7]. Secondly, it appears that the ratio of the two exposure ages (1·85) is

very nearly correct, although it may perhaps be very slightly too low. Thirdly, the value of k_2, 'the hardness value', is 2·12, which is in good agreement with the value of 2·13 obtained by Stauffer and Honda[7]. This, in turn, implies that the Treysa specimen analysed[5,7,8] came from rather less than 10 cm below the pre-atmospheric surface of the meteoroid (originally of the order of 50–100 cm in radius).

I thank Dr. Dieter Heymann for informing me of the progress of his investigation of the ^{44}Ti half-life. I thank the U.S. National Science Foundation for a post-doctoral fellowship at Bern and the Schweizerischen Nationalfonds.

Magnetic Variations produced by Ocean Swell

As part of a programme to investigate geomagnetic micropulsations, the Pacific Naval Laboratory has constructed a floating buoy for recording these signals at sea. A non-magnetic (fibre-glass) case housing a rubidium vapour magnetometer is suspended in the ocean by a nylon line from a vertical spar buoy. The system is designed to de-couple the magnetometer case so far as possible from the motion of the sea surface. The magnetometer is connected by electric cable to a raft on the surface, whence the output signals are telemetered to recording equipment on the attending ship which is kept magnetically remote from the buoy.

In connexion with such measurements, it is necessary to take into account the varying magnetic field associated with the electric currents induced in the sea-water by its motion across the Earth's magnetic field. This problem has recently been receiving some attention. For example, formulæ giving the magnetic field induced by a sinusoidal gravity wave in a deep sea have been obtained by Crews and Futterman[1] for points above the sea, and by Warburton and Caminiti[2] for points within the sea. In both these papers, the method used was to integrate the contributions from each individual current element. Actually, however, the formulæ can be found more simply by solving the differential equations satisfied by the magnetic vector $\boldsymbol{H}$ within and above the sea, and applying the usual electromagnetic boundary conditions at the surface.

Let the sea occupy the half-space $z > 0$ in a rectangular co-ordinate system, and let the gravity wave progress in the x-direction with angular frequency ω, and amplitude a at the surface. Then, with g denoting the acceleration due to gravity and $m = \omega^2/g$, the wave is specified by the velocity potential:

$$\varphi = \frac{ag}{\omega} \exp(i\omega t - imx - mz)$$

and in electromagnetic units, $\boldsymbol{H}$ satisfies the differential equation:

$$\nabla^2 \boldsymbol{H} = 4\pi\sigma \{i\omega \boldsymbol{H} - (\boldsymbol{F}.\nabla)\nabla\varphi\}$$

where $\boldsymbol{F}$ is the (constant) magnetic vector of the Earth's field, and σ is the conductivity of the medium (4×10^{-11} E.M.U. in sea-water, 0 in air). The solution for $H_\parallel$, the component of $\boldsymbol{H}$ parallel to the Earth's field (which is the component measured by a rubidium vapour magnetometer) evaluated at $t = 0$, $x = 0$, is found to be:

$$H_\parallel = amF\left\{i(S+iC)^2(1-e^{\alpha z}) - \frac{\alpha^2(S^2+C^2)}{4\pi\sigma\omega}\right\} e^{-z(m+\alpha)}$$

where $\alpha = (m^2 + 4\pi i\sigma\omega)^{1/2} - m$

and $S = \sin I$, $C = \cos I \cos\theta$

I being the dip angle, and θ the declination (eastwards) of the direction of wave propagation from the magnetic meridian. This solution is exact; it reduces to the formula obtained previously[2] if second-order terms in $\sigma\omega/m^2$ are neglected in comparison with unity. Under most conditions this is a reasonable approximation.

In both the papers to which reference has been made here the discussion was confined to wind waves of short periods, the conclusion being that quite rough seas were required to produce significant magnetic fields. For example, a sea-state 5 (1·2–1·8 m amplitude) was claimed necessary to give a field of 0·1γ at an altitude of 100 ft. (ref. 1), and even for a 100-m wave a sea-state 6 (1·8–3·0 m amplitude) is required to produce the same field at a depth of 95 m (ref. 2). However, the foregoing formula shows that $|H_\parallel|$ increases not only with the surface amplitude a of the sea wave, but also with its period $2\pi/\omega$. The variation of $|H_\parallel|$ with period (wave-length) is depicted by the curve in Fig. 1 for a depth of 100 m and a constant 1-m surface amplitude of the wave. (Other values used in the calculation were $F = 0{\cdot}56\Gamma$, $I = 70°$, $\theta = 90°$.) The sharp rise in $|H_\parallel|$ with increasing period suggests that, even on a calm sea, the long-period swell may induce magnetic fields comparable with those produced by wind waves of much larger amplitude. This important fact was apparently overlooked by many previous authors. For example, it can be seen from Fig. 1 that a 15-sec swell of only 10-cm amplitude could generate a field of 0·1γ at a depth of 100 m.

Confirmation that the ocean swell does produce appreciable magnetic signals has been obtained by recent

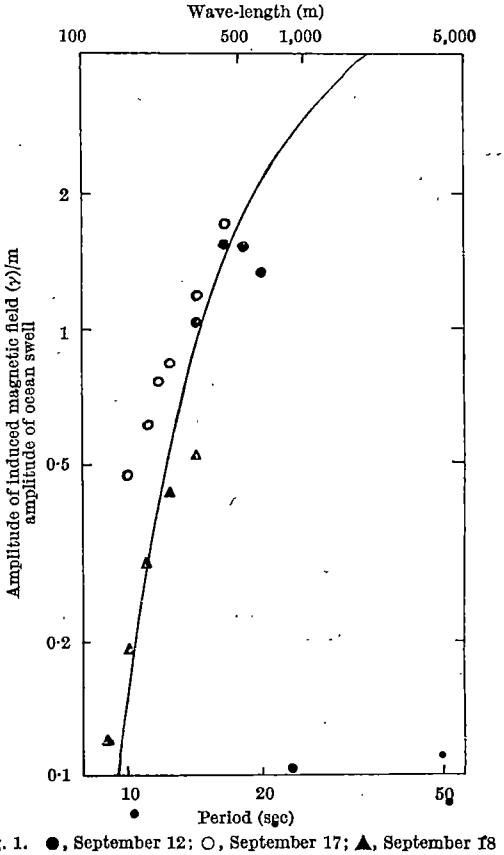

Fig. 1. ●, September 12; ○, September 17; ▲, September 18

experimental work in deep water off the west coast of Vancouver Island. Measurements were made under both calm and moderate sea conditions, but a long-period swell, measured by a vertical accelerometer fitted to the raft, was always present. On three different days the principal period of the swell (running approximately perpendicular to the magnetic meridian) was 16·7 sec, 11·8 sec and 11·1 sec, respectively, and in each case the magnetometer, suspended at a depth of 100 m, recorded a magnetic signal of approximately the same period. The power spectra and cross-correlation for the accelerometer and magnetometer signals were computed from about an hour's data for each of the three days. The coherence between the two signals was found to be very high indeed, and values of the magnetic signal per metre amplitude of the swell, which were computed for a few points in the neighbourhood of the dominant period on each of the days, were found to fit the theoretical curve reasonably well, as is shown in Fig. 1.

A further experiment was conducted to the east of Vancouver Island in Georgia Strait which is sheltered from ocean swell. A moderate sea was running at the time with short-period (3-sec) wind waves of about 0·6 m amplitude, but there was no swell. The magnetic field at a depth of 100 m was found, in this case, to be negligible (less than 0·03γ amplitude), which is also in agreement with theoretical calculations. Throughout these experiments a land-based rubidium vapour magnetometer, situated at Albert Head, on southern Vancouver Island, was used simultaneously to monitor the natural micropulsation background.

We wish to acknowledge the useful discussions with Drs. S. Z. Mack and J. E. Lokken during the planning of the experiment and the analysis of the results, and the assistance of Messrs. D. B. Edwards and J. G. Moore during the experiment.

Strontium-90 and Cæsium-137 in Antarctic Snows

THE strontium-90 content of snow samples indicates that the main influx of fission products in Antarctica occurred in 1955. The movement of ^{137}Cs seems possible in Antarctic snow.

Samples of snow were dug from the New Zealand Antarctic Division snow mine at Scott Base and after melting sent to the Institute of Nuclear Sciences, Wellington, for analysis. The results for cæsium-137 and strontium-90 content are given in Table 1 in which the errors quoted are those which arise from counting statistics only. The sample labelled 1953, for example, represents snow taken from a layer which is considered to contain the 1952/53 summer snow and the 1953 winter snow.

Table 1. FISSION PRODUCTS IN ANTARCTIC SNOWS

Year of deposit	Activity at time of deposition (picocuries/100 l.) ^{137}Cs	^{90}Sr	^{90}Sr-deposition (microcuries/km²)
1939	49 ± 28	not detected	nil
1940	268 ± 27	not detected	nil
1953	301 ± 22	34 ± 2	66
1954	89 ± 22	9 ± 1	9
1955 (summer)	74 ± 22	19 ± 1	17
1955 (winter)	91 ± 20	302 ± 3	500
1956	127 ± 18	224 ± 3	210
1957	16 ± 15	129 ± 2	
1958	50 ± 14	179 ± 2	
1959	29 ± 12	135 ± 2	
1960	not detected	100 ± 2	
1961	47 ± 13	174 ± 2	

The samples labelled 1957–1961 were collected in November 1961, the snow being melted in a kettle, poured into plastic jerricans and returned to New Zealand, where it was filtered, and carriers were added and the activities analysed. The remaining samples were collected in November 1962, melted in a kettle with carriers added to the first kettleful of each 2-gallon sample, poured into a plastic jerrican and returned to New Zealand for analysis.

This work was done with the help of officers of the New Zealand Antarctic Division, principally A. J. Heine, who dug the snow samples, and assisted with the stratigraphy and dating. He noticed that the layer he ascribed to 1955 was much thicker than other yearly layers, 58 cm as against an average of 29 cm. Therefore he took from this layer two samples of equal thickness which I have designated as 'summer' 1954/55 and 'winter' 1955 snows. Vickers[1] also mentions that 1955 produced the largest snowfall of recent years in most of west Antarctica. Heine had to rely mainly on a study of snow crystals for dating, although Sharp and Epstein[2] and Gonfiantini *et al.*[3] have since recommended the additional measurement of isotope ratios such as $^{18}O/^{16}O$. Vickers[1], however, claims that deuterium determinations and oxygen isotope ratio measurements add little to the information gained from a study of the snow crystals.

The strontium-90 determinations show a major influx of ^{90}Sr in 'winter' 1955 following smaller depositions in 1953, 1954 and 'summer' 1954/55. The latter may be due to the November 1952 'Ivy' test. The 1955 influx, arriving at least 12 months after the March 1954 'Castle' tests, is presumably due to this series. The date of this influx agrees reasonably with the arrival time of February 1955 (± 2 months) found from the total β-activity measurements of Picciotto and Wilgain[4] on snows from a glaciological pit at King Baudouin Base. The ^{90}Sr determinations of Libby[5] and Drevinsky[6], which were discussed by Vickers[1], indicate increases at Admiral Byrd Bay, Atka Bay, Kainan Bay and McMurdo Sound in the spring/summer of 1954—somewhat earlier than shown by our results. Furthermore, Drevinsky's Kainan Bay figures appear lower than those at other stations and show a further major increase about spring 1955. It seems that further measurements coupled with accurate pit stratigraphy at different sites in the Antarctic are still desirable.

Our cæsium-137 results appear completely chaotic. The low figures for both strontium-90 and cæsium-137 in the 1957–61 samples may reflect the absence of carriers during melting and transport. The nearly constant $^{137}Cs/^{90}Sr$ ratio of about 1·8 almost invariably found in rain samples is not apparent. Furthermore, appreciable ^{137}Cs was found in the 1939 and 1940 samples—13 years before the first thermonuclear device was detonated in November 1952. The ^{137}Cs results suggest, therefore, either contamination, or migration of ^{137}Cs in Antarctic snows. These possibilities are being investigated.

The absolute values recorded in Table 1 must be regarded with caution. A complete profile is being re-sampled with greater precautions to melt the snow in the presence of carriers. The ^{90}Sr results for the 1957–1961 snows have been included in Table 1 because, although we suspect them to be low, they are still much higher than the pre-1955 values.

GEOCHEMISTRY

Luminescence of Orthopyroxenes

In an examination of several stony meteorites Derham and Geake[1] reported on the luminescence of three enstatite achondrites under proton excitation. A later report[2] concludes that enstatite, the major mineral in the meteorites, is probably responsible for all the observed luminescence. Each meteorite yields a spectrum in which red emission with a peak at 6700 Å is accompanied by a weaker blue peak at 4000 Å. The red peak at 6700 Å in meteoritic enstatite has been attributed by Garlick[3] to $MgSiO_3$ containing manganese as an impurity. Sarver and Hummel[4] have shown that both photo- and cathodo-luminescence occur in the red spectral region (6310–6830 Å) of Mn-activated magnesium germanates and silicates. The position of peak emission of enstatite activated with Mn(II) is extrapolated from $MgGeO_3$–$MgSiO_3$ enstatite solid solutions to be 6730 Å. This is near the value found in synthetic clinoenstatite activated with Mn(II), namely, 6720 Å. By examining crushed grains of the Bustee meteorite, Derham, Geake and Walker[2] were able to separate grains which luminesced blue from a mixture in which most of the grains luminesced red. The luminescence spectrum of the 'blue' grains differs from that of the 'red' grains and from the luminescence spectrum of the meteorite in that the red peak at 6700 Å is weaker than the blue peak at 4000 Å. X-ray powder analyses of 'red' and 'blue' grains showed both to be orthoenstatite.

Recent investigations[5,6] have shown that orthoenstatite in enstatite achondrites is present in both ordered and disordered forms. We have made a preliminary examination of luminescence of orthopyroxenes and related minerals in an attempt: (1) to delimit the occurrence of this phenomenon in a number of diverse samples; (2) to show whether any correlation exists between luminescence and disorder in $MgSiO_3$.

Samples were excited by X-rays from a tungsten tube operated at 50 pkV and 35 m.amp. Luminescence was observed visually for overall colour and through appropriate filters to obtain a crude estimate of the red and blue components of the emission. X-ray single crystal and powder techniques were utilized to investigate disorder in the orthopyroxenes. The results of this survey are presented in Table 1.

Mg-silicates prepared in different laboratories from different starting materials yield similar luminescence. With the possible exception of the Stannern hypersthene, luminescence was observed only in orthopyroxenes containing little or no iron. None of the four terrestrial iron-bearing orthopyroxenes, all from plutonic environments, emits detectable luminescence. The presence of an appreciable amount of iron in the $MgSiO_3$ structure may inhibit the luminescence which is readily apparent in the virtually iron-free synthetic and meteoritic enstatites.

All the disordered orthopyroxenes examined exhibit luminescence, but there is no simple correlation between disorder and the intensity and colour of the light emitted. Differences in luminescence were found between ordered and disordered enstatites from the same meteorite (Khor Temiki and Pena Blanca Spring in Table 1). In both cases the luminescence of the disordered enstatite was weaker and the ratio of blue to red was higher. This suggests that some correlation does exist between the character of the luminescence and either disorder in the structure or some effect closely related to and perhaps cogenetic with disorder.

Note. In a communication which reached us just before this letter was submitted for publication, Dr. Geake informed us of his later work at Manchester on the Bustee meteorite. The X-ray powder patterns of 'red' and 'blue' grains from this meteorite[2] have been found by Prof. W. S. MacKenzie to match those of ordered and disordered orthoenstatite, respectively.

Table 1

Sample	Meteorite class or source	Structural state of orthopyroxene	Luminescence

PHYSICS

Aggregation of Ice Crystals in Strong Electric Fields

A RECENT series of experiments[1] has demonstrated that the adhesion of ice crystals on collision is a sensitive function of temperature, humidity and crystal-type. However, the effect of electric fields on the adhesion was not examined. Electric fields may have an important effect on the aggregation of ice crystals to form snowflakes inside thunder-clouds where the crystal concentrations are high and fields of several thousand V/cm have been measured. It appeared possible that the attractive forces between the crystals, produced by polarization charging within the field and accentuated because of the small radius of curvature of the crystal edges, may produce increased aggregation which would be especially important under conditions close to the threshold, in the absence of a field, between adhesion and separation. The experiments described here were performed in order to test this hypothesis.

Ice crystals were formed at a predetermined temperature inside a cold room[2] by producing a water cloud and seeding it with pellets of solid carbon dioxide. While the crystals were growing inside the cold room, small water drops of known identical diameter were suspended from the tips of fine glass fibres located centrally within two identical ebonite tubes (Fig. 1), and were then frozen by exposing them to a stream of cold crystal-free air. The ebonite tubes were located on top of the cold room, and the cooling stream was produced by passing air through copper coils surrounded by solid carbon dioxide. Windows inserted in the walls of the ebonite tubes permitted visual observation or photography of the spheres by means of a telescope. A variable high-voltage source, connected between two electrodes in the form of copper rings straddling one of the ice spheres, allowed this sphere to

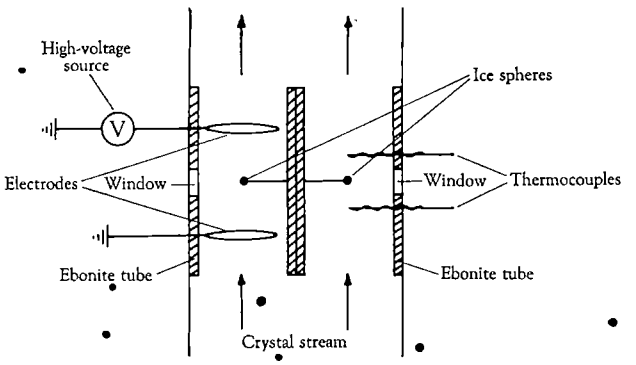

Fig. 1. Apparatus for measuring the aggregation of ice crystals in electric fields

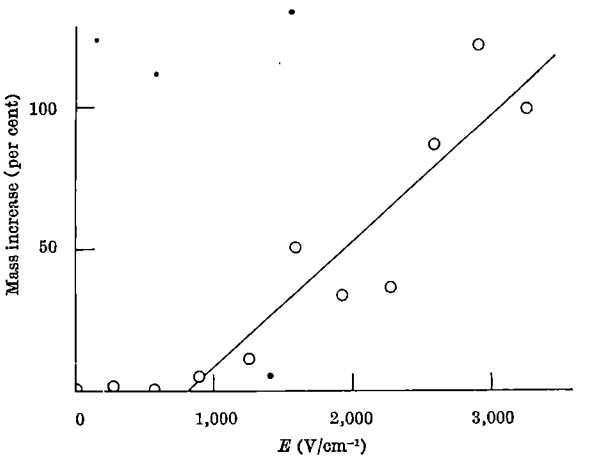

Fig. 2. The increase in mass of an ice sphere as a function of electric field strength E. Temperature of the crystal stream, − 9° C

be exposed to an electric field of up to about 4,000 V/cm^{-1} along the direction of the axis of the tubes. Subsidiary experiments showed that the field in the vicinity of the ice sphere could be calculated approximately by dividing the potential difference between the electrodes by their separation. In addition, the electrodes were found to have no appreciable effect on the crystal flow; dummy electrodes, not shown in Fig. 1, were situated inside the field-free tube in order to minimize differences between the air-flow inside the two tubes. The temperature at various points in the vicinity of the spheres was measured by means of thermocouples. The temperature of the air flowing past the spheres was continually adjusted in order to maintain that of the crystals inside the cold room. The rate of flow of air past the spheres could be controlled by varying the voltages applied to suction devices, and was measured by means of flow-meters.

When the ice crystals had been formed, the subsidiary cooling circuit was switched off and ice crystals were immediately drawn from the cold room to flow at a known speed past the two ice spheres, one of which was suspended in an electric field of pre-selected strength. The collection of ice crystals by the spheres was then observed through the telescope for the entire duration of the exposure of the ice spheres to the crystal streams. At the end of each experiment the crystal stream and electric field were switched off, and the aggregates of ice crystals and the spheres to which they adhered were melted by exposing them to a current of warm air of low velocity. The diameter of the two resultant water drops was measured using a micrometer eyepiece in the telescope and the mass increase of both drops was calculated from these measurements and a knowledge of the initial diameter of the drops.

Fig. 2 shows that although there was a large amount of scatter in the individual readings there was a definite increase in aggregation with increasing electric field. For field strengths below about 800 V/cm^{-1} there was no detectable difference between the masses collected by the two spheres but for higher fields the mass collected by the sphere situated inside the field was considerably greater than that collected by the sphere in the field-free tube. The visual observations confirmed these mass-charge measurements. If the electric field was below about 800 V/cm^{-1} the underside of the ice sphere collected a highly compact assemblage of ice crystals which was similar to that adhering to the ice sphere in the field-free tube. However, for higher fields, long chains of ice crystals protruded from the underside of the ice sphere (probably along the lines of force) and often attained a length of several hundred μ before folding inwards to adhere to other folded chains of crystals and thus creating a very open three-dimensional structure. Occasionally one of

the longer chains would be torn away from the ice sphere by aerodynamic forces; this probably accounts to a great extent for the large amount of scatter in the individual readings of increase in mass.

These experiments demonstrate that ice-crystal aggregation is appreciably influenced by the presence of strong electric fields. However, more comprehensive investigations are required in order to establish the influence of fields of thunderstorm magnitudes on ice-crystal aggregation under all the conditions of temperature, humidity and crystal-type which are of meteorological importance.

Directional Property of Electrode Surfaces

It has been recognized for several years that when a conducting electrode is placed in an electrolyte in which there is an alternating potential gradient, it can assume a potential different from that expected[1]. In particular, it is generally found that the electrode potential is out of phase with the potential in the electrolyte by a variable amount. So far as I know, no explanation has been offered for the effect.

It is clear that it can occur only if the Helmholtz double layer at the electrode/electrolyte surface is non-uniform in the direction of the applied potential gradient, so that currents which pass from the electrolyte through the layer to the material of the electrode, and back into the electrolyte at a point of lower potential, are, electrically speaking, asymmetrical. Fig. 1 shows the section and plan of an irregular, non-uniform electrode, the surface of which is level with that of the insulating material in which it is embedded, the whole surface forming the boundary with an electrolyte in which there is a potential gradient E_z, unchanged by the introduction of the electrode. The electrode material is supposed to have a specific conductance high compared with that of the double-layer specific acceptance, so that the electrode potential is everywhere U_e, while the potential at the origin is arbitrarily taken as zero. The thickness of the double layer is small compared with the electrode dimensions, so that little error is introduced by assuming that current flow in the layer is everywhere normal to its surface.

With these assumptions, and noting that

$$\int_A j_y \mathrm{d}A = 0$$

where A is the total electrode area and j_y the current density normal to the electrode surface at any point, it follows that:

$$\int_{-a}^{a} w_z \sigma_z \, (U_e - E_z z) \, \mathrm{d}z = 0$$

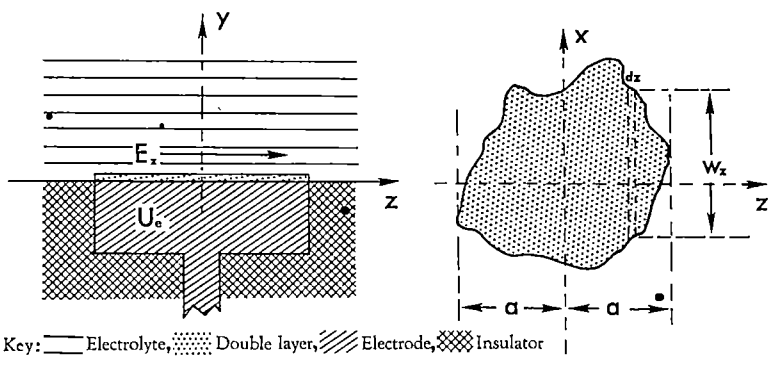

Fig. 1

where w_z is the length of a strip, dz, of electrode surface, and σ_z is the average admittance of the strip. Now both $w_z\sigma_z$ and U_e can be complex, and writing these $(p + iq)$ and $(U_p + iU_q)$ respectively $(i = \sqrt{-1})$, and solving the simultaneous equations which result from separation of the real and imaginary parts, it is found that:

$$\frac{U_q}{E_z} = \frac{\int_{-a}^{a} qz\mathrm{d}z \Big/ \int_{-a}^{a} q\mathrm{d}z - \int_{-a}^{a} pz\mathrm{d}z \Big/ \int_{-a}^{a} p\mathrm{d}z}{\int_{-a}^{a} p\mathrm{d}z \Big/ \int_{-a}^{a} q\mathrm{d}z + \int_{-a}^{a} q\mathrm{d}z \Big/ \int_{-a}^{a} p\mathrm{d}z}$$

$$\frac{U_p}{E_z} = \frac{\int_{-a}^{a} pz\mathrm{d}z \Big/ \int_{-a}^{a} q\mathrm{d}z + \int_{-a}^{a} qz\mathrm{d}z \Big/ \int_{-a}^{a} p\mathrm{d}z}{\int_{-a}^{a} p\mathrm{d}z \Big/ \int_{-a}^{a} q\mathrm{d}z + \int_{-a}^{a} q\mathrm{d}z \Big/ \int_{-a}^{a} p\mathrm{d}z}$$

Thus the quadrature component U_q is zero only when the centroid of the double-layer conductance coincides with the centroid of its parallel susceptance. Two obvious special cases are (*a*) p/q = constant, and (*b*) when both p and q are even functions of z. The results bear a close relationship also to the simple capacity bridge. Further, U_p is zero only in case (*b*).

The magnitudes of the components can quickly be assessed by considering the simple case of a rectangular electrode having its centre at the origin and its axes coincident with 0z, 0x. Let p be constant and equal to p_0, while q has values:

$$\begin{array}{rl} q_0 & -a < z < 0 \\ (1+\alpha)q_0 & 0 < z < a \end{array}$$

Then if $p_0 \approx q_0$ and α is small:

$$U_q \approx U_p \approx \alpha E_z a/8$$

and if $E_z = 2$ mV/cm, $a = 0{\cdot}025$ cm, $\alpha = 0{\cdot}1$, $U_q \approx U_p \approx 1$ μV.

The effect has been examined experimentally by rotating about their axes, relative to the potential gradient in the electrolyte, electrodes of 0·5 mm dia., and observing values of U_q and U_p at different angles. Typical plots of U_q using an electrode of bright gold are shown in Fig. 2. The effect is observed also with platinized electrodes, and a simple method has been discovered to make the surfaces reproducibly directional. The electrodes are platinized with their surfaces vertical, and the effect of gravity on the heavy platinum ions during electro-deposition is such as always to result in the double-layer asymmetry being along the vertical diameter. When platinization is carried out with the electrode surface horizontal, no asymmetry results. No surface variations of electrodes in good condition can be discerned under a low-power microscope (×40) whether or not asymmetry is found; on the other hand, any surface irregularity which can be discerned (for example, in damaged electrodes) can usually be related, from its angular position on the electrode surface, to the results of a rotational experiment.

The simple theory given here is inadequate when the current flow through the double layer is sufficient to produce a significant potential drop in the electrolyte. (This is true, for example, of platinized electrodes in 0·45 per cent sodium chloride solution.) In this case a quadrature potential gradient, which may be measured by means of an exploring probe, is produced in the electrolyte. If a pair of diametrically opposed electrodes are used, and the conducting medium between them be asymmetrical, an interelectrode quadrature potential is observed; and this would

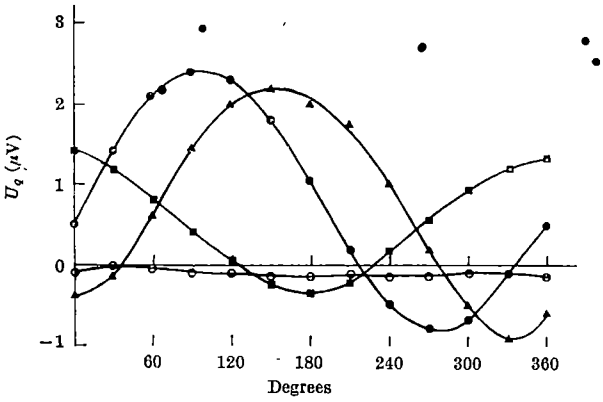

Fig. 2. ● Bright gold, 0·45 per cent NaCl; ▲ the same, after rubbing electrode surface along 0–180° diameter; ■ gold, platinized with 150°–330° diameter vertical; ○ gold, platinized with electrode surface horizontal

$E_z = 2{\cdot}2$ mV/cm, frequency 240 c/s.

be so even if the electrode surfaces were perfectly uniform. It appears to be this effect, and not that due to surface asymmetry of the electrodes, which has been observed by Hognestad[2].

The effect of surface asymmetry can be greatly reduced (as Schwan found) by fitting the electrode in a recess in the insulating wall, thus reducing the potential gradient at the electrode surface. A more detailed account of the experimental work, carried out in connexion with baseline errors in electromagnetic flowmeters for recording blood flow, will be given elsewhere.

Laser Excitation of Powdered Solids

An understanding of the physical processes which occur when solids are subjected to intense surface heating is important to meteor and re-entry physics and to the physics of comets. These processes have been investigated spectroscopically in the laboratory by shock excitation[1,2], flash photolysis[3,4] and the impact flash[5]. As shown by Stoicheff[6], the high temperatures obtainable by using a focused ruby laser beam provide yet another means for the excitation of solids. It is the purpose of this note to report briefly on the spectroscopic investigations which have been made on laser excitation of molecular spectra from powdered solids during the past two years.

A commercial ruby laser with a nominal output of 2·5 joules and a pulse duration of 500 μsec has been used in this work. The beam is focused to a 0·5 mm diameter spot on the surface of the powder sample by an inexpensive microscope objective. The surface power density is thus about 3 MW cm^{-2}. Spectra of the 'flame' produced by the laser beam were recorded photographically in the wave-length range 2000 Å–7000 Å by Hilger *f*/4 Raman quartz and constant deviation glass spectrographs. The latter instrument was fitted with a 'Polaroid' camera back in place of its conventional film holder.

The powdered solid target materials used here were superior in performance to non-powdered solids because of their greater surface area, lower reflectivity and lower thermal diffusivity. Since most of the powders have also been shock excited[2], comparison between the two methods of excitation is possible.

The materials investigated and the gross features of their laser-excited spectra are displayed in Table 1. In all cases the experiment was performed in air at atmospheric pressure. As Debras-Guedon and Liodec[7] have

Table 1. Molecular Spectra produced by Laser Excitation of Powdered Solids in Air

Material	Observed molecular spectra*	Remarks
Al	AlO : Blue-Green ($A^2\Sigma^+ - X^2\Sigma^+$), UV($B^2\Pi - X^2\Sigma^+$)	Very strong

* Spectra cited in the same manner as by Pearse and Gaydon[9].

discussed laser-excitation of atomic spectra, the atomic features of our spectra are not listed in Table 1. All spectra were relatively free from overlapping continuum. No molecular spectra were observed when BeO, Bi, Cd, Mg, MgO, Pb, and S respectively were used as targets for the focused laser beam.

The strong preponderance of oxide band systems observed is consistent with the oxidizing atmosphere in which they were excited and supports the belief that much of the molecular spectrum arises from chemical reactions in the flame. This view is also supported by the work of Howe[8], who observed that the C_2 emission from laser-excited carbon begins promptly with onset of the laser pulse, while the accompanying CN emission is delayed by 15 μsec. It is interesting to note that the white powders, BN, TiO_2, CaS, give rise to laser-excited spectra while some black powders, Si, PbS, do not.

Intensity measurements are now being made on the molecular spectra to determine vibrational and rotational temperatures. Time-resolved investigations are also being made.

We thank Dr. B. Stoicheff for helpful discussions. The work is supported by grants from the Air Force Office of Scientific Research (*AF–AFOSR* 62–236*A*) and from the National Aeronautics and Space Administration (*NSG* 349).

Annealing Behaviour of Recoil Cobalt-57 Atoms in Hexammine Nickel Chloride

Recoil chemistry of ^{57}Co (half-life: 270 days) produced by the (γ,p) reaction or by the decay processes (β^+ and *EC*) in hexammine nickel chloride has not been studied so far. In this work, studying behaviour of recoil ^{57}Co atoms in the nickel complex on thermal annealing, I have found remarkable difference between annealing reactions of ^{57}Co atoms produced by the $^{58}Ni(\gamma,p)^{57}Co$ reaction and those of ^{57}Co produced by the decay processes of ^{57}Ni.

Hexammine nickel chloride $Ni(NH_3)_6Cl_2$ was prepared by the orthodox method and recrystallized in concentrated ammonia[1]. $Ni(NH_3)_6Cl_2$ labelled with ^{57}Ni (half-life: 36 h) was prepared in the same way as aforementioned starting from metallic nickel powder irradiated by γ-rays of 20 MeV. γ-Rays were generated by an electron linear accelerator (maximum energy: 20 MeV, mean beam current: 30 μamp). The target material was irradiated while being cooled by dry ice. Radiation decomposition was minimized by cooling (< about 1 per cent). Chemical forms of ^{57}Co were analysed by a cation exchanger column ('Diaion *SK* 1', 100–200 mesh, 1 cm × 7 cm), after dissolving the irradiated complex in 0·1 N hydrochloric acid. The Co^{2+} fraction was further separated from Ni^{2+} or $Ni(NH_3)_6^{2+}$ using an anion exchange column ('Diaion *SA* 100', 100–200 mesh, 1 cm × 3 cm) under strongly acid condition (> 8 N HCl). By these procedures principal chemical forms of ^{57}Co could be separated satisfactorily[2]. Radioactivity of ^{57}Co samples was measured by a 20-channel γ-ray spectrometer of the Baird-Atomic Instrument Co.

The distribution of recoil species thus analysed is listed in Table 1. In the case of the (γ,p) reaction, Co^{2+} (or its precursor) changes into $Co(NH_3)_5Cl^{2+}$ and $Co(NH_3)_6^{3+}$ on thermal annealing at 87° C. Especially increase of the $Co(NH_3)_5Cl^{2+}$ fraction is the main event in this case. On the decay processes, however, the main event on thermal annealing is increase of $Co(NH_3)_6^{3+}$, which corresponds to the decrease of Co^{2+} (or its precursor). For the samples standing at room temperature, distribution of recoil products shows similar tendency to the annealed one.

These phenomena seem to be very important in interpreting annealing behaviour of recoil cobalt atoms because ^{57}Co recoil chemistry in nickel complexes eliminates possibilities of guided reactions to the parent species which are usually observed in ^{60}Co recoil atoms produced by the (n,γ) reaction. In this sense, annealing of ^{57}Co atoms is free from guiding to the parent species in the damaged zone in the crystal.

The reason why increase of $Co(NH_3)_5Cl^{2+}$ is the main event on annealing of ^{57}Co atoms produced by the (γ,p) reaction will be understood by considering a fairly large fragmentation zone around the ^{57}Co recoil atoms (maximum recoil energy: ~ 0·2 MeV). Annealing reactions here can be interpreted to be of synthetic type among the fragments such as Co^{2+}, Co^{3+}, $Co(NH_3)_x^{2,3+}$, NH_3, Cl^0, Cl^-, etc. Therefore, remarkable increase of $Co(NH_3)_5Cl^{2+}$ occurs by recombination of fragments.

In the case of ^{57}Co atoms produced by the decay processes fragmentation will be very small, and electronic change around ^{57}Co atoms will be important, because recoil energy of the atoms on the decay processes is small (maximum: 34 eV), and charge distribution will be created on the decay processes[3]. As in Wertheim's observation[4], a recoil cobalt atom will finally acquire +2 or +3 valence state in the crystal in very short time after the decay processes. At least some percentage of decayed ^{57}Co will remain in the chemical forms of $Co(NH_3)_6^{2+}$ or $Co(NH_3)_6^{3+}$, leaving electronic defects around the decayed atom. Annealing reaction in this region will be mainly of electronic type. For example, $Co(NH_3)_6^{2+}$ (unstable in an aqueous solution) will be converted into $Co(NH_3)_6^{3+}$ (stable in an aqueous solution) by giving up one electron to the neighbouring electronic defects. This possibility has already been discussed by Harbottle and myself[5,6]. In Table 1, increase of $Co(NH_3)_6^{3+}$ on annealing of decayed ^{57}Co atoms will most probably be interpreted by change of its electronic state. The difference between the main tendencies in annealing behaviour of ^{57}Co produced by the (γ,p) reaction and that of the decayed atom will be a good indication of two types of annealing reactions: one, a synthetic type, and the other, an electronic type.

I thank Dr. N. Shibata for his discussions, Mr. M. Hara and Mr. H. Nozaki for their assistance.

Jets from Imploding Bubbles

Bowden has suggested that micro-Munro jets may play a part in the initiation of non-homogeneous explosive systems[1]. In addition, he and Brunton have shown that such jets can be formed by impacting a vessel containing a liquid with a hemispheric cavity located on its surface[2]. In an investigation of possible mechanisms for the initiation and propagation of low-velocity detonations in a cavitated liquid explosive, we have investigated the formation and subsequent behaviour of jets from bubbles in water and nitroglycerin–ethylene glycol dinitrate (NG–EGDN).

In these experiments, roughly hemispherical cavities were formed on the surface of the liquid under an overlay of vinylidene chloride film having a thickness of 0·0006 in. The cavities were then collapsed by a shock wave derived from a tetryl donor and attenuated by an aluminium plate 0·75 in. thick.

Selected views from a framing camera sequence showing water micro-jets are presented in Fig. 1. In this trial, a 1-in. diameter × 1-in. long tetryl donor was used; the depth of water, contained in a transparent tank with the attenuator serving as a base, was 1 in. In frame 2 of the sequence, a hemispherical shock wave can be seen approaching the four bubbles in the left side of the container. The

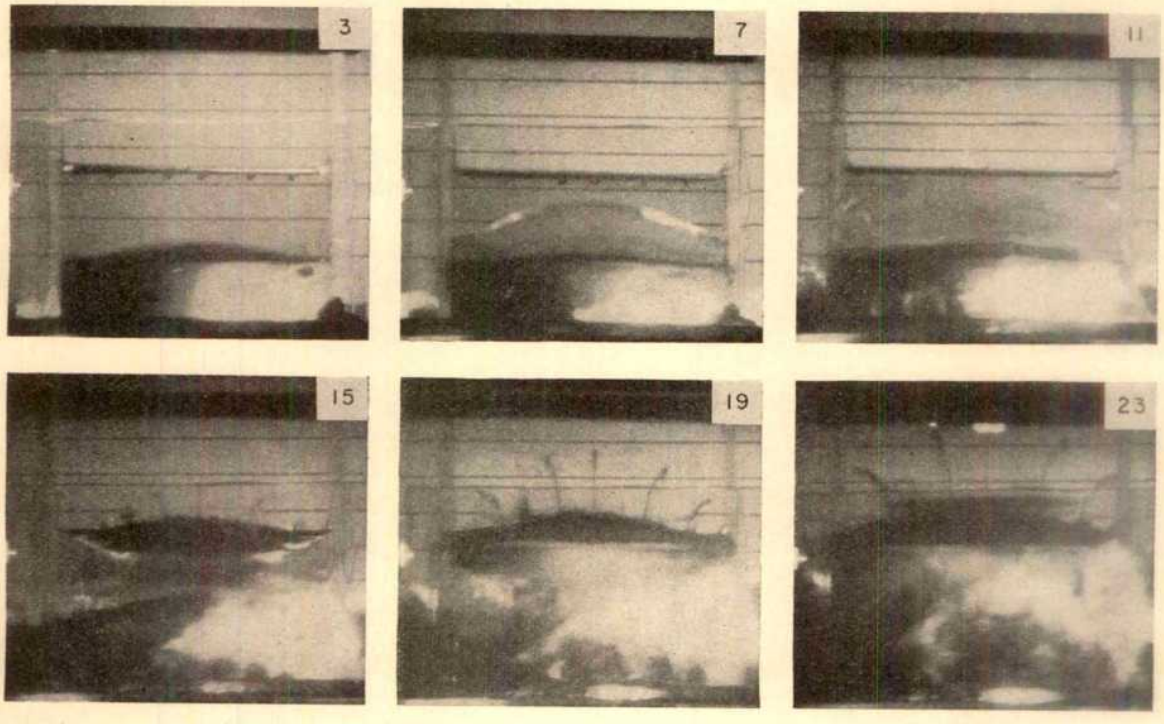

Fig. 2. Micro-jets of NG–EGDN impacting an aluminium barrier; the interframe time was 1 μsec

shock strength at this point, estimated from independent experiments, is approximately 10 kilobars. Frames 6, 10, 14 and 18 clearly show that each of the cavities produces a high-velocity jet. It will be noted that the velocity of the jets is strongly influenced by the divergence of the shock front. The velocity of the fastest jet, which can be seen striking a 0·25-in. aluminium barrier in frame 22, is estimated to be 1·9 mm/μsec. Subsequent examination of the barrier showed distinct pitting as a result of jet impact. It has been suggested[2] that the damage of solids by 'cavitation' is due in some part to this type of impact. Micro-jets of adequate velocity to produce 'cavitation' damage might arise from the interaction of two or more neighbouring cavities where the shocks generated by the collapse of one would serve to produce jetting in others.

Several frames from a sequence of a similar trial using NG–EGDN are shown in Fig. 2. In this case a $1\frac{5}{8}$-in. diameter × $1\frac{1}{2}$-in. long tetryl donor was used with a liquid fill of 0·5 in. The peak shock strength, inadequate for the initiation of a high-velocity detonation in NG–EGDN, is estimated to be approximately 38 kilobars when it enters the fluid; it has decayed to about 20 kilobars when it

encounters the cavities. Again, as in the case of the trial using water, each of the cavities produces a high-speed jet. Furthermore, while initially non-luminous and presumably non-reacting, each of the jets was observed to react explosively when it impinged on the aluminium barrier. Two such reactions can be seen in frame 23. The velocity at impact of the central jet is approximately 2·5 mm/μsec, which yields a peak impact pressure estimated to be in excess of 100 kilobars. Since for NG–EGDN this pressure is adequate for the initiation of a high-velocity detonation, the explosion in impact observed here can well result from shock heating.

These observations are believed to be especially pertinent to the initiation and propagation of a low-velocity detonation in liquid explosives. Earlier work conducted at the Bureau indicated that cavities played an important part in the initiation of liquid explosives[3]. More recent investigations have shown that cavities are generated by precursor waves propagated through container walls in the case of stable low-velocity detonations. These cavities serve as initiation centres, and while the exact initiation mechanism is not known micro-jetting appears to be a likely one. The results of this investigation into the nature of low-velocity detonations will be reported later.

CRYSTALLOGRAPHY

Crystal Structure of Manganese *Cyclo*pentadienide

The crystallographic constants of manganese *cyclo*pentadienide[1] indicate that the crystal structure of this compound is different from those of other ferrocene-type molecules. Elucidation of its structure is imperative for an explanation of the strong metal–metal interactions found to exist in the crystals of manganese *cyclo*pentadienide. Magnetic measurements performed by Cotton, Wilkinson and Birmingham showed the crystals to be antiferromagnetic with a Néel temperature of 134° K (ref. 2).

A crystal of manganese *cyclo*pentadienide was obtained by vacuum sublimation and introduced in a Lindemann glass capillary in a nitrogen atmosphere. Its morphology was similar to that described by Weiss and Fisher[1], and the cell dimensions and systematic absences as determined by iron and molybdenum equi-inclination Weissenberg and precession photographs are essentially identical to those previously published: $a = 28{\cdot}03 \pm 0{\cdot}03$ Å, $b = 11{\cdot}74 \pm 0{\cdot}02$ Å, $c = 9{\cdot}96 \pm 0{\cdot}01$ Å, $\alpha = \beta = \gamma = 90°$, $Z = 16$; $hkl : h + k = 2n$, $0kl : k + 2l = 4n$, $h0l : h = 4n$, $hk0 : h = 2n$, and $k = 2n$ only. The space groups $Cm2a$ and $Cmma$ are consistent with the observed absences but do not allow for all of them. Moreover, it is impossible to find an acceptable arrangement of the 16 molecules in the unit cell consistent with both the symmetry and the additional absences.

The following observations indicate that the apparent orthorhombic symmetry results from the twinning of monoclinic crystals.

(1) High-order reflexions with both h and $k \neq 0$ on Fe $K\alpha$ $hk0$ and $hk1$ Weissenberg pictures are split, indicating that the observed pattern is a superposition of two almost orthogonal reciprocal lattices related by a mirror plane perpendicular to the common axis. The size of the splitting is consistent with a γ angle of 90° 17′.

(2) The three-dimensional Patterson map calculated from $hk0$–$hk8$ Mo $K\alpha$ Weissenberg and $0kl$ molybdenum $K\alpha$ precession camera data can only be interpreted as the superposition of two Patterson maps related by a mirror plane // (100) (or // (010)).

The relationship between the orthorhombic and the primitive monoclinic cell is shown in Fig. 1. The cell dimensions of the latter are: $a = 15{\cdot}20 \pm 0{\cdot}02$ Å, $b = 11{\cdot}74 \pm 0{\cdot}02$ Å, $c = 9{\cdot}96 \pm 0{\cdot}01$ Å and $\gamma = 114° 46' \pm 3'$. Though transformation of indices and co-ordinates from the large C centred cell to the monoclinic cell is straightforward we have found it convenient to refer indices and co-ordinates to the almost orthogonal C-centred cell.

The primitive monoclinic cell has the space group $P2_1/b$ ($Z = 8$) (c unique), which allows for the absences of $hk0$ with h and/or k odd and of $00l$ with l odd (indices refer to C-centred cell). The additional absences of the $0kl$ and $h0l$ reflexions require that the two molecules in the asymmetric unit are related as x, y, z and $\frac{1}{4} - x$, $y + \frac{1}{4}$, $z + \frac{1}{2}$. Manganese co-ordinates consistent with this condition could be derived from the Patterson map; they are:

$x_1 = 0{\cdot}033_5$	$y_1 = 0{\cdot}027$	$z_1 = 0{\cdot}25$
$x_2 = 0{\cdot}21_5$	$y_2 = 0{\cdot}277$	$z_2 = 0{\cdot}75$

These positions are shown in Fig. 1. Short Mn^{++}–Mn^{++} vectors are found in a plane roughly parallel to (100), the distance between two manganese ions related by the centre of symmetry at the origin being 5·36 Å, while the ions related by the b glide plane are 5·87 Å away from each other (almost equal to the 5·91 Å a axis translation in ferrocene[2]). In a direction perpendicular to the (100) plane all Mn^{++}–Mn^{++} distances are greater than 7·3 Å. This arrangement suggests that the anomalous magnetic properties of manganese *cyclo*pentadienide result from interionic interactions within the layers // (100) and it predicts a two-dimensional magnetic ordering in the anti-

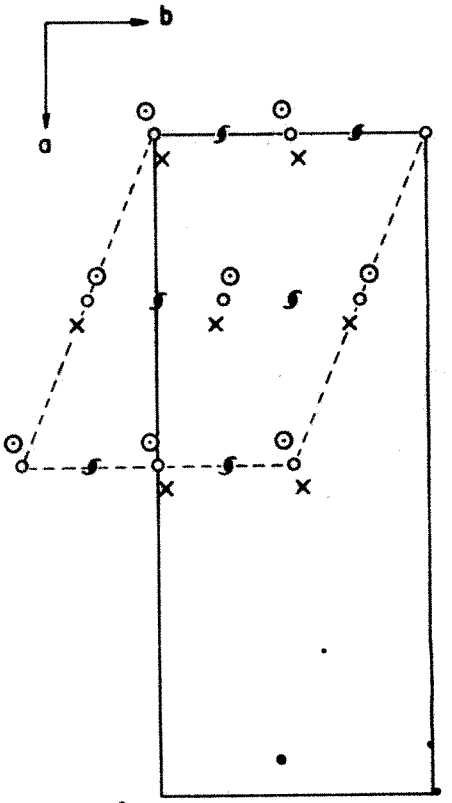

Fig. 1. Relationship between the two unit cells and the positions of the Mn^{++} ions. ×, Mn^{++} at or close to $z = 0{\cdot}25$; ○, Mn^{++} at or close to $z = 0{\cdot}75$

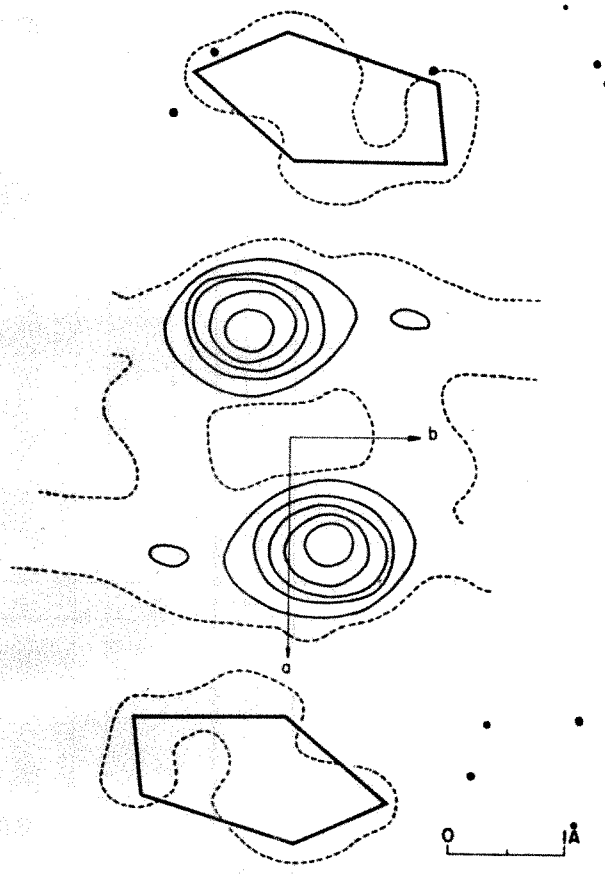

Fig. 2. *hk*0 Fourier map with Mn^{++} signs only. Contours at arbitrary intervals, zero contour broken. Maxima corresponding to ring atoms are seen on both sides of the large peaks representing Mn^{++} ions. One of these rings is drawn, the other overlaps the Mn^{++} peak

ferromagnetic state, similar to the ordering observed in Cu formate tetrahydrate[4,5].

As a result of the twinning an observed intensity I_{hkl} is a sum of the intensities of the hkl and $h\bar{k}l$ reflexions. Thus, for hkl reflexions one cannot obtain values of F_{hkl} by applying the usual correction values. However, it can be shown that for $h = 2n$, $k = 2n$, $|F_{hkl}| = |F_{h\bar{k}l}|$. Since the $hk0$ level contains only such reflexions it is possible to calculate the $hk0$ Fourier map in the usual way. This map, with signs based on Mn^{++} contributions only, is shown in Fig. 2.

Unresolved maxima appear which can be identified as the *cyclo*pentadienide rings. As anticipated, these rings are roughly parallel to the layers containing the short Mn^{++}–Mn^{++} vectors.

The details of the arrangement of the carbon atoms are as yet uncertain: a further investigation of the structure is in progress.

I thank Dr. D. R. Christman for preparing a sample of manganese *cyclo*pentadienide.

This work was carried out in part under the auspices of the U.S. Atomic Energy Commission.

CHEMISTRY

Significance of the Solubility of Hydrogen Halides in Mercaptans and Thioethers

The low ideal (Raoult's law) solubility of hydrogen chloride has revealed the factors determining the real solubility of hydrogen chloride in a considerable number of compounds. From the data on the solubility expressed as moles of HCl per mole of an organic compound containing oxygen there appears to be a remarkable correlation between the solubility and the basic (or hydrogen bonding) function of the oxygen atom[1]. Extension of this work to observations on certain sulphonyl compounds[2] naturally led to the examination of mercaptans and thioethers. Solubility of hydrogen halides (HCl, HBr and HI) in these compounds concerns the basic or hydrogen bonding function of the sulphur atom.

Solubilities were determined by weighing the maximum amount of hydrogen halide absorbed at atmospheric pressure by about 2 g of compound in a U-tube at 0°. Although in previous investigations the solubilities were determined over ranges of temperature (see ref. 1 for refs. to particular papers), in this initial investigation of the sulphur compounds the temperature was maintained at 0°. In Table 1 are expressed the solubilities as moles of H*X* per mole of sulphur compound at 0°. The purity of each compound was checked by boiling point and gas-liquid chromatography, and after absorption of H*X* the compound was recovered by water treatment and so identified with the original compound.

Available results for the corresponding oxygen compounds are given in Table 1. For alcohols such as *n*-butanol the solubility of hydrogen chloride at 0° is more than 1 mole/mole, and although the solubilities in the corresponding mercaptans are much smaller they are materially larger than the corresponding ideal value, and point to a specific 'association' between sulphur and H*X*. To draw a line of demarcation between hydrogen bonding and basic function of a donor atom is a matter of definition, and we do not enter into this controversy here.

Table 1. Solubilities (moles of H*X* per mole of substance) at 0°

Substance	HCl	HBr	HI
Ideal	0·041	0·691	0·370
n-Decane	0·049	0·10	0·37

* Thiophene
† Tetrahydrothiophene
‡ Reacts further
§ White solid formed (see text).

Whenever the phenyl group is attached to oxygen, not only in phenol but also in phenyl esters, the basic function of oxygen is greatly reduced as compared with the corresponding *n*-butyl system. This effect is attributed to mesomerism involving an oxygen lone pair of electrons and the π-system of the ring[1]. A similar effect is clearly reflected in the thiophenol and diphenyl sulphide examples.

The dialkyl sulphides show lower solubilities for HCl than do the alcohols, but the solubilities are still much greater than ideal. Unfortunately data for HBr and HI are not available for the alcohols because of further quick enough reaction to give alkyl halides; but the sulphides show remarkably high solubilities, and it is a matter for further investigation to elucidate in precise terms the mode of 'association'.

Solubilities in thiophene are very low; but in tetrahydrothiophene the dialkyl sulphide value appears again for HCl. However, in the examples of HBr and HI a white crystalline solid was obtained at the 1 : 1 mole

ratio. By a suitable control in the passage of HBr, and by holding the temperature between 0° and about 20°, it appeared that if the actual formation of crystals was avoided, much more HBr was absorbed.

There have been diverse opinions on the hydrogen bonding function of the SH group with reference to donor molecules[3], and evidence for sulphur as the donor atom in hydrogen bonding is sparse[4]. In consideration of the increasing spectroscopic attention being given to hydrogen bonding and related basic function, the solubility data now presented give justification for further examination of sulphur compounds, particularly as the results might have a bearing on the function of sulphur in protein chemistry.

Photochemistry and Radiation Chemistry of Fluorobenzene in Aqueous and Other Solutions

One of the problems in the radiation chemistry of solutions, and aqueous solutions in particular, is whether the chemical changes observed are due to ionization processes and free radical formation, or to excitation processes (which would resemble photochemical reactions). In a previous investigation[1] we discussed the action of ionizing radiations, compared with that of ultra-violet light on aqueous solutions of benzene. It was shown that in this case the action of ionizing radiations led to the formation of products different from that of ultra-violet light and, in particular, the *p*H-dependence of the two processes was entirely different. It was thus possible to differentiate between the two reaction mechanisms and to show that at least in dilute solutions excitation processes do not significantly contribute to the effects of ionizing radiations.

We have now investigated the related case of fluorobenzene. This was chosen since fluorine, as an aromatic substituent, has properties which in many aspects resemble those of hydrogen. In particular, the bond energy C—F on aromatic carbon is even stronger (115 ± 3 kcal) (ref. 2) than the aromatic C—H bond (102 kcal). The absorption spectrum of fluorobenzene in aqueous solution scarcely differs from that of benzene itself. The solubility of fluorobenzene in water is like that of benzene.

On the other hand, fluorine in aqueous solution, if displaced from the aromatic bond, would form the negative F^- ion accompanied by the gain of energy due to high electron affinity of the F-atom and the high solvation energy of the fluoride ion. If hydrogen is displaced at all, it should form the positive H^+ ion. Work on the radiation chemistry of organic fluorine compounds has generally indicated lack of reactivity[3]. It was now found when aqueous solutions of fluorobenzene were irradiated in the presence of oxygen, with ionizing radiations from a 200 kVp X-ray set, that F^- was formed in the solution with a *G*-value which was somewhat influenced by the *p*H varying from about 3·35 at *p*H 1·2 to about 1·6 at *p*H 8·4. This relatively high *G*-value of fluoride formation was accompanied by the formation of hydrogen peroxide showing a change with *p*H from 2·1 at *p*H 1·2–1·5 at *p*H 8·4. When irradiations were carried out in the absence of oxygen, the *G*-value of fluoride formation was

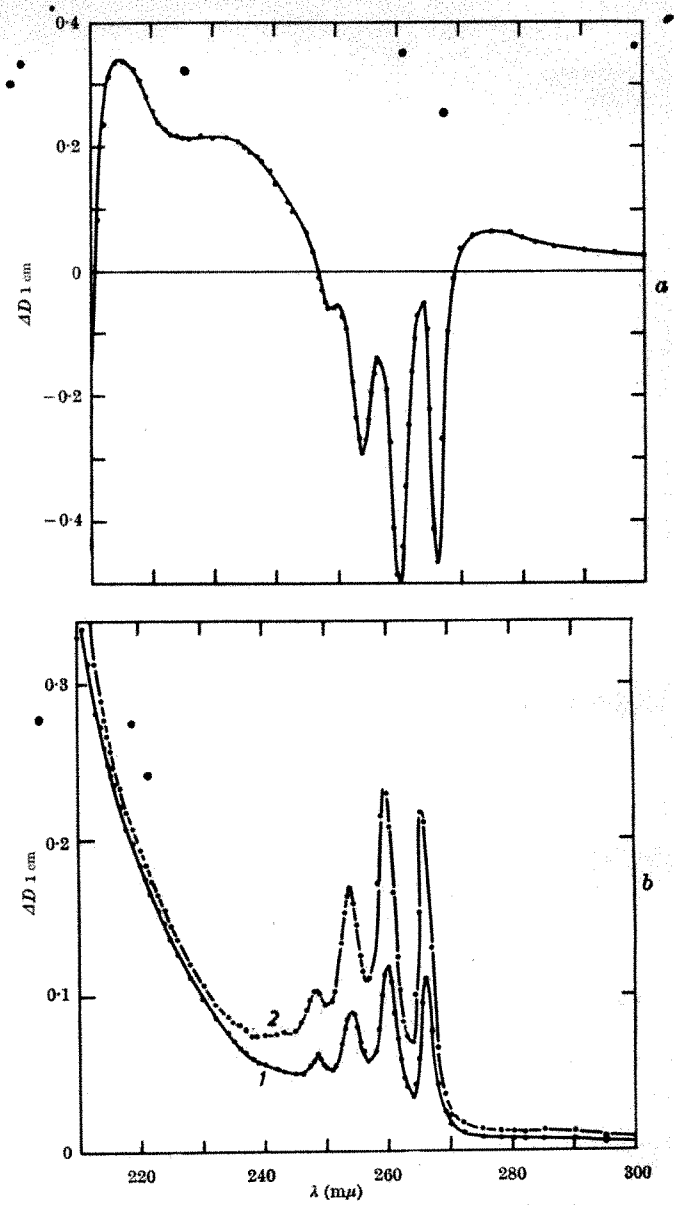

Fig. 1. Difference spectra obtained in 1 cm path-length optical cells of $9{\cdot}5 \times 10^{-4}$ M solution of fluorobenzene in ethanol. *a*, Difference between solution irradiated at 2537 Å *in vacuo* with $1{\cdot}2 \times 10^{-5}$ einstein/ml. and unirradiated solution; *b*, difference between irradiated solution after contact with air for (1) 1 h and (2) 19 h and the same solution before admission of air

4·55 at *p*H = 3·1 while that of hydrogen peroxide formation decreased to approximately 0·6. These results are entirely consistent with efficient displacement of fluoride from the aromatic ring both by OH radicals and by solvated electrons and H atoms. The high yields are to be noted in view of the low solubility (about 0·1 per cent or 0·01 molar) in aqueous solution.

By comparison on illuminating aqueous solutions of fluorobenzene in the presence or in the absence of oxygen with ultra-violet light of 2537 Å, it was found that the quantum yield of fluoride formation had the relatively low value of approximately 0·015, changing little with *p*H. It was found, however, that in these photolysed solutions another process proceeded with greater efficiency in oxygen-free solutions, leading to the disappearance of the absorption band of fluorobenzene in the 260 mμ region. This photochemical change had a quantum yield of more than 0·2 and was almost entirely reversible on admission of oxygen. No evidence for such effects was obtained using ionizing radiations.

In order to gain further information concerning the nature of this reaction, we investigated the process using solutions of fluorobenzene in ethanol or *n*-heptane as well. Here, too, a similar disappearance of the band due to fluorobenzene was observed, the change being largely reversible on admission of oxygen. The quantum yields are lower at comparable concentrations in ethanol and heptane than in water. We investigated the dependence of quantum yields on fluorobenzene concentration in the non-aqueous solvents and found results which, allowing for the number of quanta absorbed, indicated a first-order dependence on concentration. Therefore, the results would be consistent with a formation of a dimer. In view of previous results in the literature[4], it is not impossible that strongly polar fluorine might facilitate the formation of dimers containing, for example, *cyclo*butane rings. However, we have no definite evidence on this point and hope to elucidate this further.

We thank Prof. E. Lippert for his advice. One of us (L. M. R.) thanks the International Atomic Energy Agency, Vienna, for a fellowship.

Production of Hydrogen in the Radiolysis of Methanol Vapour

DURING an investigation of the radiolysis of methanol vapour Baxendale and Sedgwick[1] quantitatively accounted for all product yields in terms of those initial ionization processes observed in the mass spectrometer[2], where the important reactions have been shown to be:

$$e^- + CH_3OH \rightarrow CH_3OH^+ + 2e^- \quad (1)$$

$$\rightarrow CH_2OH^+ + H + 2e^- \quad (2)$$

$$\rightarrow CHO^+ + H_2 + H + 2e^- \quad (3)$$

They further assumed that as a result of reactions such as:

$$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + \cdot CH_2OH \quad (4)$$

and:

$$CH_2OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_2O \quad (5)$$

the only important neutralization process is:

$$CH_3OH_2^+ + e^- \rightarrow CH_3OH + H \quad (6)$$

The foregoing ion-molecule reactions have been observed in the mass spectrometer by Lindholm[3]. The species e^-, H and $CH_3OH_2^+$ can therefore be considered the probable precursors of hydrogen. It was further suggested that the methanol molecule formed in reaction (6) is in an excited state and dissociates to molecular hydrogen and formaldehyde.

It has been found possible to identify H and e^- in the liquid phase radiolysis of both alcohols and water by the use of appropriate solutes. In the work recorded here we have attempted a similar approach in the gas phase, using nitrous oxide, methyl bromide and propylene as potentially efficient scavengers.

Irradiations were carried out with 260-kV electrons produced in single pulses of 0·2 μsec duration from a modified C.S.F. klystron unit coupled with a Field Emission Corporation pulser, model 233. The absorbed dose of 10^{17} eV per pulse was determined using nitrous oxide at 165 mm mercury pressure as dosimeter, assuming $G(N_2) = 9{\cdot}68$ (ref. 4). Air-free samples of methanol were irradiated at a pressure of 200 mm mercury and a temperature of 40°–42° in a 3-l. 'Pyrex' cell fitted with a 10μ thick stainless steel window. Methanol (Merck reagent grade) was purified as described previously[5]. Methyl bromide, nitrous oxide and propylene were purified by trap-to-trap distillation. The product gases were removed from the methanol after irradiation and the yields were determined by gas-solid chromatography.

The following yields were obtained for pure methanol:

$$G(H_2) = 10 \pm 2 \quad G(CH_4) = 0{\cdot}5 \pm 0{\cdot}1 \quad G(CO) = 1{\cdot}0 \pm 0{\cdot}2$$

These are the mean values for ten experiments investigated over the range 4×10^{17} eV/g to 5×10^{18} eV/g, the higher doses being obtained by accumulation of successive pulses. They are in good agreement with those of Baxendale and Sedgwick, apart from the methane yield which is appreciably higher.

The reactions:

$$N_2O + e^- \rightarrow N_2 + O^- \quad (7)$$

and:

$$CH_3Br + e^- \rightarrow \cdot CH_3 + Br^- \quad (8)$$

have been shown by electron impact investigations to occur effectively at or near zero electron energies[6–8]. In the methanol system these reactions will result in the production of nitrogen and methane respectively in the presence of the two additives, with a corresponding reduction in the hydrogen yield. However, the addition of up to 1 per cent v/v nitrous oxide was found to have no effect on $G(H_2)$, and the nitrogen yield, after correction by electron fraction for direct absorption by the solute, was found to be $G(N_2) < 0{\cdot}1$. In the presence of up to 3 per cent methyl bromide again no reduction in $G(H_2)$ was observed and $G(CH_4)$ remained constant. We therefore conclude that, at the highest additive concentrations used in this work, neutralization processes such as reaction (6) are not affected.

Alkyl halides are known to be efficient H atom scavengers in the liquid phase, and in the case of methyl bromide the reaction is:

$$CH_3Br + H \rightarrow \cdot CH_3 + HBr \quad (9)$$

The constancy of $G(H_2)$ and $G(CH_4)$ yields observed further suggests that there is no appreciable contribution to the hydrogen yield from thermal H atoms.

Previous work[1] has shown that in the presence of less than 1 per cent benzene the hydrogen yield is half that observed in pure methanol. It was suggested that benzene both scavenges H atoms and quenches excited methanol molecules. It was pointed out, however, that the latter mechanism would require a long-lived excited state of methanol and, in the light of our experiments with methyl bromide, the former mechanism appears less attractive. Because of the low ionization potential of benzene the following charge transfer reaction may also be important in the radiolysis of methanol–benzene mixtures:

$$CH_3OH^+ + C_6H_6 \rightarrow CH_3OH + C_6H_6^+ \quad (10)$$

This reaction is exothermic to the extent of 1·6 eV (ref. 9), and in order to compete favourably with reaction (4) it requires a very high rate constant.

We have found that propylene also reduces the hydrogen yield. In the presence of 0·03 per cent v/v propylene $G(H_2) = 5{\cdot}6$, that is, the efficiency of propylene is approximately 40 times higher than that of benzene. At 1 per cent v/v and 2 per cent v/v propylene $G(H_2) = 1{\cdot}9$, in agreement with the limiting or 'molecular' yield found using benzene[1]. The corresponding charge transfer reaction between C_3H_6 and CH_3OH^+ is also exothermic to the extent of 1·1 eV (ref. 9). In contrast, the charge transfer reactions involving nitrous oxide and methyl bromide are respectively endothermic to the extent of 2 eV and approximately energetically neutral[8].

By extending this work in the methanol system to a wide variety of additives, we intend to test this apparent correlation between ionization potential and the ability of the solute to affect the radiolytic yields.

BIOCHEMISTRY

Electron Microscope Investigation of Lactic Dehydrogenase Agent

The lactic dehydrogenase (LDH) agent, detectable by increased levels of plasma or serum LDH in inoculated test mice, was found in association with a variety of transplanted murine tumours by Riley *et al.*[1]. Various estimations of its size by filtration methods have been suggested. These include diameters of 2 mμ, approximately 45 mμ, and 55 mμ (refs. 2, 3 and 4, respectively). In an attempt to resolve these conflicting observations, electron microscopic investigations of the LDH agent were initiated, and this report describes preliminary findings.

Three pools of heparinized blood were obtained from *C57BL/Fg* mice 24–36 h after an intraperitoneal injection of 0·1 ml. of a preparation containing $10^{3 \cdot 5}ID_{50}$/ml. of the LDH agent. Plasma was collected by centrifugation at 2,000 r.p.m. for 20 min, diluted with an equal volume of Eagle's basal medium, and centrifuged for 5 min at 9,000 r.p.m. The supernatants were then spun at 105,000*g* for 2 h in a Spinco 'Model L' ultracentrifuge and the pellets removed. For controls, plasma was obtained from non-treated *C57BL/Fg* mice and a pellet prepared as described. A pellet was also prepared from a filtrate (100 mμ 'Millipore' filter) of a human carcinoma of the breast which does not contain the LDH agent[5]. Ice was used throughout and each centrifugation was at 0° C. One pellet, prepared from infected mouse plasma, was resuspended to its original volume; the infective titre was determined to be $10^{10}ID_{50}$/ml. Pieces cut from the remaining four pellets were fixed in 1 per cent osmic acid with veronal buffer (*p*H 7·4), dehydrated, and embedded in methacrylate. Thin sections were cut with glass knives on a Porter–Blum microtome and mounted on 'Formvar'-coated grids. These were stained for 5–10 min in lead citrate and examined in an RCA '*EMU-3C*' electron microscope.

Fig. 1 illustrates the typical appearance of particles found in thin sections from pellets of infected mouse plasma. They are oval-shaped and measure approximately 15 mμ in width and 45 mμ in length. As evidence that these particles are the LDH agent, it should be noted that: (*a*) their length, 45 mμ, is identical with the diameter calculated by Rowson *et al.*[3] from filtration data; and (*b*) similar particles were not seen in preparations of control pellets.

The above observations, and other findings derived from investigations of its epizootiology and properties[4,6], suggest that the LDH agent is a virus. Since this communication was completed, Bladen and Notkins[7] have reported an electron microscope investigation which demonstrates that the LDH agent is an essentially spheroidal particle measuring 69 mμ × 76 mμ in diameter. The techniques used by these investigators were similar to ours with the exception that their material was examined by negative staining. This variable could account in part for these discrepancies, but it is of interest to consider the possibility that the confusion which now exists as to the size of the LDH agent may be due to a failure to recognize that there is more than one agent.

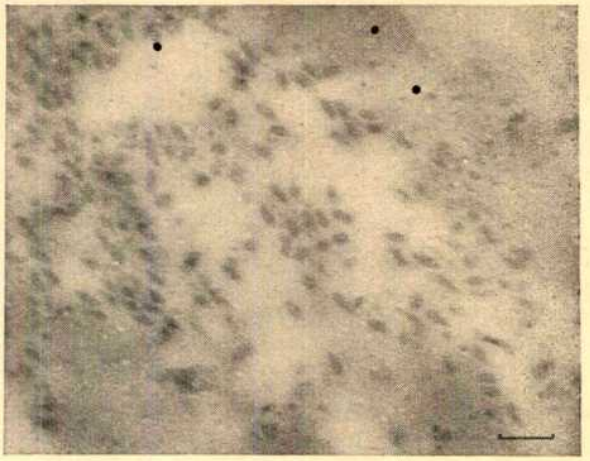

Fig. 1. Electron micrograph of pellet prepared from mouse plasma infected with the LDH agent showing oval-shaped particles (× *c.* 22,700). Line at lower right represents 100 mμ

Interaction of Cytochrome *c* with Yeast D(−) Lactic Oxidase

In 1961 Gregolin and Singer[1] reported that yeast respiratory particles, prepared by mechanical disruption of cells in 1 per cent NaCl, do not oxidize D(−) lactate with oxygen as the terminal electron acceptor. However, the particles exhibit strong D(−) lactic dehydrogenase activity, and oxidize D(−) lactate with oxygen uptake on addition of external cytochrome *c*. More recently, Gregolin and D'Alberton observed[2] that D(−) lactate is oxidized at high rate by oxygen when respiratory particles are prepared by disintegration of the cells in sucrose solution. When tested in a medium known to give maximal oxidase activity, the oxidation is not stimulated by addition of cytochrome *c*. In the presence of the same mixture (plus NaN_3), D(−) lactate is not oxidized by this preparation with cytochrome *c* as artificial electron acceptor.

In simultaneous and independent work, Roy[3] noticed an analogous ineffectiveness of cytochrome *c* on a D(−)

lactic oxidase system, obtained by using a French pressure cell. He presented two hypotheses to explain the different behaviour of his preparation as compared with that by Gregolin and Singer, namely, 'duality' of species or sites of action of cytochrome *c* and solubilization of cytochrome *c* by NaCl. The hypotheses were not substantiated and the problem remained unanswered in Roy's report.

The present communication proposes an alternative explanation, namely, that the inactivity of cytochrome *c* on D(−) lactic oxidase preparations is mainly due to limitations of assay. Indeed, the best conditions to show full D(−) lactic oxidase activity are not those in which cytochrome *c* interacts with the system. Cytochrome *c* does react with the D(−) lactic oxidase obtained from mechanically broken cells, if proper assay conditions are chosen. The same is possibly true for particles prepared by the pressure cell. However, in the latter case it is also possible that cell disruption by pressure, rather than by mechanical treatment, leads to a preparation of more intact respiratory particles, inaccessible to cytochrome *c*.

The following experiments, which support this suggestion, were performed with particles prepared by mechanical breakage and isolated in 0·25 M sucrose with 0·001 M EDTA and 0·02 M potassium phosphate, *p*H 7·3, according to the procedure previously described[2].

When tested under optimal conditions for full D(−) lactic oxidase activity, that is, at *p*H 6 and in the presence of 0·035 M Mg^{2+}, the particles do not exhibit any particular response to cytochrome *c* (Fig. 1, exp. *A*). When Mg^{2+} is absent, the activity with D(−) lactate is much slower, and cytochrome *c* exerts a stimulatory effect, but not sufficient to raise the rate of oxidation to the level obtained in the former case (exp. *B*). That this effect is not due to restoration of a normal level of cytochrome *c* in particles is suggested by the fact that succinic oxidase activity is not stimulated by cytochrome *c* (exp. *C*).

Exp. *D* was performed in the reaction medium reported by Roy[3]. In this case the oxidation of D(−) lactate was less efficient than in the medium used in exp. *A* and cytochrome *c* showed only a very modest stimulatory effect.

It would appear that the inactivity of cytochrome *c*, in exp. *A*, is a consequence of the presence of Mg^{2+}, due either to the high ionic strength of the medium, or because Mg^{2+} restores the normal flow of electrons from the primary dehydrogenase to oxygen.

Table 1. D(−) LACTATE OXIDATION BY YEAST RESPIRATORY PARTICLES WITH VARIOUS ELECTRON ACCEPTORS AND UNDER DIFFERENT ASSAY CONDITIONS

Electron acceptor	μMoles D(−) lactate oxid./min/mg protein: In the reaction medium for oxidase assay	Under optimal conditions for each test	In the medium described in ref. 3
Oxygen		0·10	0·07
Phenazine methosulphate	0·30	0·39	0·32
Cytochrome *c*	0·007	0·1	0·015

Oxygen uptake was measured polarographically, phenazine methosulphate and cytochrome *c* reduction spectrophotometrically. The reaction medium for D(−) lactic oxidase was: 0·05 M potassium phosphate, *p*H 6, 0·035 M $MgCl_2$, 0·01 M D(−) sodium lactate. The medium for reduction of cytochrome *c* and phenazine methosulphate was: 0·05 *M tris*-HCl, *p*H 7·5, 0·01 M D(−) sodium lactate, according to Gregolin and Singer[4]. Sodium azide (5×10^{-3} M) was added in spectrophotometric assays. Activities with cytochrome *c* and phenazine methosulphate are expressed at V_{max} for the electron acceptors. Temperature, 22° C.

Table 2. OXIDATION OF D(−) LACTATE BY YEAST PARTICLES PREPARED BY DIFFERENT PERIODS OF CELL DISINTEGRATION

Time of breakage	μMoles D(−) lactate oxid./min/mg protein: Oxygen	Phenazine	Cytochrome *c*	Ratios of activities: Oxygen / Phenazine	Oxygen / Cyt. *c*	Cyt. *c* / Phenazine

Particles were prepared as described in the text, with the exception of the disintegration step, which lasted as indicated. Activities were determined as in Table 1.

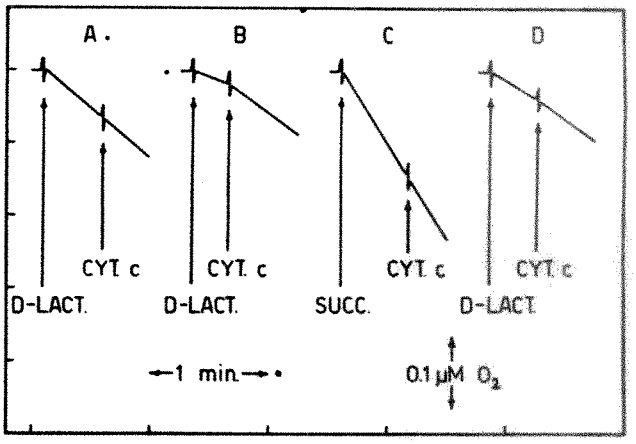

Fig. 1. Polarographic determinations of D(−) lactate and succinate oxidation rates by yeast respiratory particles. Experiments *A* and *B* were performed in 0·05 M potassium phosphate, *p*H 6, 0·035 M $MgCl_2$; exp. *C* in 0·05 M *tris*-HCl, *p*H 7·5; exp. *D* in 0·3 M mannitol, 0·01 M potassium phosphate, *p*H 7·2, 0·01 M potassium chloride and 0·005 M magnesium chloride, according to Roy[3]. D(−) sodium lactate was 0·01 M, sodium succinate 0·02 M, cytochrome *c* 2×10^{-4} M. Amounts of particles corresponding to 4 mg protein were added, suspended in 0·2 ml. of 0·25 M sucrose. Total volume, 2·0 ml. Temperature, 22° C

The influence of the assay conditions on the phenomenon is made clear by spectrophotometric measurements of the rate of reduction of cytochrome *c*. The activity was assayed under optimal conditions for this test, and compared with the rate in the media used for oxidase activity (plus NaN_3). Table 1, where D(−) lactate oxidation rates with oxygen and with phenazine are included for comparison, shows that cytochrome *c* reductase activity is normal in particles prepared in 0·25 M sucrose. However, either at *p*H 6 in the presence of Mg^{2+}, or in the medium used by Roy, it is almost completely suppressed, while phenazine activity is only slightly affected. It must be emphasized that under no conditions is the rate of cytochrome *c* reduction stimulated by Mg^{2+}, meaning that no reduction of 'external' cytochrome *c* takes place through a pathway which requires Mg^{2+} and includes 'internal' cytochrome *c*.

When the time of exposure of the yeast cells to the breakage treatment was varied, the respiratory particles showed different ratios between D(−) lactic dehydrogenase and D(−) lactic oxidase activities (Table 2). Cytochrome *c* reductase activity accompanies oxidase activity. However, particles obtained in very short periods of disruption are proportionately less active with cytochrome *c* than with phenazine. This finding suggests that cytochrome *c* is hindered in its approach to the active site by permeability or accessibility barriers. Depending on the time of cell breakage, the specific activity of the oxidase in the particles falls more quickly than that of the dehydrogenase. This is possibly due to disintegration of the complex structure of the oxidase system under mechanical treatment.

Finally, it must be added that the reactivity of external cytochrome *c* with the D(−) lactic dehydrogenase does not constitute proof that this carrier is the natural electron acceptor of the enzyme.

Enzymatic Oxidation of Galactose-6-phosphate

Galactose-6-phosphate (gal-6-P) has been shown to be produced from galactose-1-phosphate (gal-1-P) in the presence of phosphoglucomutase[1], demonstrated in erythrocytes of patients with galactosæmia[2], and oxidized in the presence of purified glucose-6-phosphate dehydrogenase (G-6-PD) and NADP as indicated by changes in absorbance at 340 mμ (ref. 3). This communication shows that G-6-PD purified from either yeast or human erythrocytes in the presence of NADP converts gal-6-P to 6-phosphogalactonic acid (6-P-gal A).

For the work described here, the G-6-PD from human erythrocytes was isolated by fractionation on DEAE-cellulose and precipitation with ammonium sulphate resulting in about a 200-fold increase in specific activity from the original hæmolysate[4]. This preparation was free of 6-phosphogluconate dehydrogenase (6PGD) activity. The G-6-PD from yeast was obtained from Sigma Co. Incubation was carried out using 5 mmoles of gal-6-P, 0·5 m.moles of NADP, 0·375 m.moles of magnesium chloride, 10 mg of methylene blue and 700 units (one unit equals reduction of 1·0 μM NADP/min at *p*H 7·4 and 25° C) in a final volume of 1 l. of 0·06 M *tris* buffer, *p*H 7·5. The reaction was maintained at 37° C in the case of enzyme from erythrocytes and at 30° C when using enzyme from yeast. After incubation for 15 h, the reaction was stopped by the addition of cation exchange resin ('Dow 50 × 8, H^+', 60–100 mesh) and the nucleotides were removed with activated carbon ('Darco *G*-60') (ref. 4). The oxidation product was isolated by using a column of anion exchange resin ('Dow 1 × 8, Cl^-', 200–400 mesh), eluting with 4 l. of hydrochloric acid over a linear *p*H gradient of from 4·0 to 1·5 and collecting 20-ml. fractions. Fig. 1 shows that after incubation for 15 h, approximately 50 per cent of the reducing sugar remained in reaction mixtures using enzymes prepared from either yeast or erythrocytes; all remained when enzymes were not added. On fractionation of the incubation mixture on an anion exchange resin column, the material eluted at *p*H 1·7 was non-reducing and positive for glyoxalate and glycolaldehyde after periodate oxidation. After crystallization at *p*H 5·7 as the barium salt, the final yields were 257 and 107 mg using enzymes prepared from yeast and erythrocytes, respectively.

The preparations of phosphorylated aldonic acids were compared with 6-P-gal A. The 6-P-gal A used as the reference compared was synthesized by bromine oxidation of gal-6-P (Nutritional Biochemicals, Ohio, Batch No. 6450, $[\alpha]_D^{25} = +24{\cdot}4°$) (ref. 5), the product isolated by fractionation on a column of anion exchange resin ('Dow 1 × 8, Cl^-', 200–400 mesh), and crystallized as the barium salt. Comparison was carried out using a descending system of ethanol–ammonium acetate (1·0 M, *p*H 7·5) (5 : 2 v : v) developed for 48 h (ref. 6) and of ethyl acetate–pyridine–water (2 : 1 : 1 v : v : v) developed for 18 h and visualized with the periodate permanganate reaction[7]. Neither preparation showed either fluorescence or absorption with ultra-violet light, and after staining with periodate permanganate yielded single densities having mobilities corresponding to authentic 6-P-gal A.

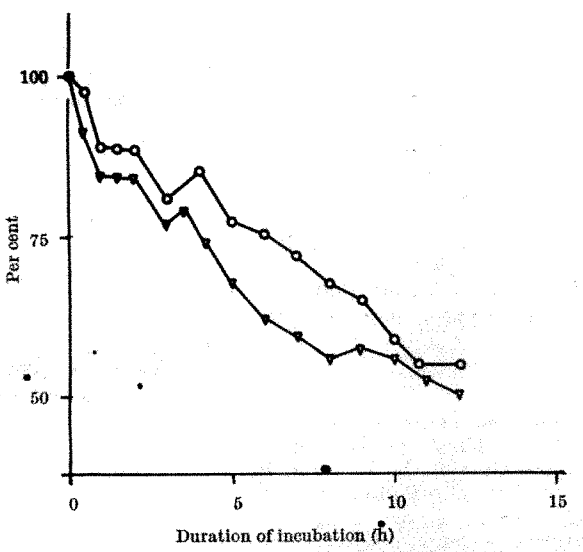

Fig. 1. Results showing the conversion of gal-6-P to 6-P-gal A. The reaction was followed by determining the reducing sugar and expressing remaining reduced sugar as per cent of the initial amount. Results from human erythrocytes are shown as triangles and from yeast as circles

Table 1

* 6-Phosphogluconic acid.
† Glyoxalate produced by periodate oxidation and reacted with diphenylamine.
‡ Absorbance at 260 mμ is converted to quantity using the coefficient of $18{\cdot}0 \times 10^3$.

When the phosphorylated aldonic acids were subjected to periodate oxidation and reacted with diphenylamine[8], bluish-green solutions were obtained. Their absorption spectra had two maxima, one at 440 mμ attributed to the reaction of glyoxalate with diphenylamine and another at 660 mμ resulting from the reaction of glycolaldehyde with diphenylamine. The spectrum from 350 to 700 mμ for the two preparations was identical, and similar to that produced by authentic 6-P-gal A and 6-phosphogluconic acid.

The analyses of the two preparations are summarized in Table 1. The results are compared with those for 6-P-gal A synthesized by bromine oxidation and 6-phosphogluconic acid (6-P-GA) obtained commercially. The data are expressed in mμmoles/100 μg of preparation. There is an equimolar relationship among the organic phosphate, the glyoxalate and the glycolaldehyde groups. The positive glycolaldehyde reaction after periodate oxidation indicates substitution of the primary alcohol of the aldonic acid; the positive glyoxalate reaction indicates the presence of a carboxyl group. The ratio of about 3 for periodate uptake to glyoxalate suggests three pairs of vincinal, unsubstituted hydroxyl groups. These results indicate that the carboxyl group has replaced the reducing group and that the carbon structure of gal-6-P is otherwise intact.

The phosphorylated aldonic acids were hydrolysed in the presence of alkaline phosphatase[9] and the resulting aldonic acids were isolated by fractionation on a column of anion exchange resin. When the products were chromatographed on paper using a system of ethyl acetate–pyridine–water, densities corresponding to authentic galactonic acid were observed after staining with periodate permanganate. The products were also acetylated in the presence of cadmium hydroxide, acetic anhydride and hydrogen chloride, crystallized from ethyl alcohol–chloroform and twice re-crystallized from toluene. All the preparations had melting points of 131° C compared with the literature value of 131°–132° C for D-galactonic acid pentaacetate.

The preparations of 6-P-gal A were tested for oxidation in the presence of NADP and hæmolysate as the source of 6-PGD. The change of absorbance at 340 mμ as a function of time was compared with that observed using 6-phos-

phogluconate as substrate. The rate of the former was about 65 per cent of the latter.

Recently, results have been published suggesting that some patients with galactosæmia show variability in the manifestations of the condition on both a clinical[9,10] and biochemical[11–13] basis. The possibility that this oxidation pathway may play a part in determining these differences is being investigated.

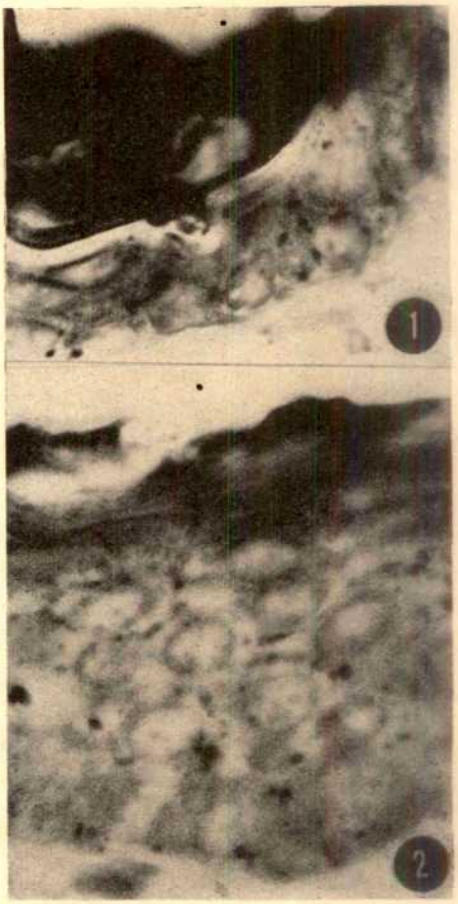

Fig. 1. Epidermis of a normally-fed *BUB* female mouse stained with sudan black *B* (× 870)

Fig. 2. Epidermis of *BUB* female mouse deficient in essential fatty acid, coloured with sudan black *B* (× 870)

Lipids in the Skin of Mice Deficient in Essential Fatty Acids

THE lipids of the skin are affected markedly by the dietary condition of the animal[1,2]. In rats kept on a fat-free diet the skin retained more fat than any of the other organs including, for example, the liver and muscle[3,4]. The epidermis of fatty-acid deficient rats is thicker and more differentiated than that of normal rats, the stratum granulosum is distinct and the stratum corneum is thick[5]. In this communication the lipid content of the skin of mice which were deficient in essential fatty acids is compared with that of normal mice.

Two groups of *BUB* female mice were used. One group consisted of essential fatty-acid deficient mice kept on a fat-free diet for 11 weeks. The diet was composed of Fenton's casein No. 4, 5 g; vitamin-free test casein, 15 g; dextrose, 72 g; salt mix No. 2, 4 g; non-nutritive fibre, 4 g. The other group was of mice kept on an ordinary diet and served as controls. Pieces of skin from the back, the ear and the upper lip were fixed in formal-calcium, post-chromed and embedded in gelatin according to Baker's[6] acid hæmatin routine. Frozen sections, 5–10μ thick, were cut on a cryostat, and some of them were coloured with sudan black *B*[7] and the others were stained with acid hæmatin[6].

The skin of mice deficient in essential fatty acid is thicker than that of normal ones. However, the most striking difference between the two groups is in the epidermis. In all the regions examined, the epidermis of mice deficient in essential fatty acids is nearly three times thicker than the epidermis of normal mice (Figs. 1 and 2). Three different zones are detected in the stratum malpighii: the stratum basal, the stratum spinosum and the stratum granulosum. In normal mice, the stratum malpighii consists of a layer, only 1–2 cells thick. In the experimental animals, the stratum corneum is thicker and more compressed than in normal animals. Sudan black colouring shows that cells of the stratum malpighii contains many more lipid granules in the experimental than in the control animals. Lipid is especially abundant in the stratum granulosum which is laden with sudanophilic granules (Fig. 2). The stratum corneum is coloured to the same degree with sudan black in both groups, and there is no obvious difference between the two groups of animals in the morphology or the stainable lipid of the sebaceous glands. Sections stained with acid hæmatin did not reveal any significant difference in the phospholipid contents of the epidermis in normal mice and those deficient in essential fatty acids.

Accordingly, the excess lipid granules observed in the skin of experimental animals are not phospholipids and they cannot be sterols, since the latter do not usually stain with sudan black at room temperature[8]. It is likely, therefore, that the additional lipids in the epidermis of deficient mice are mainly in the form of glycerides and free fatty acids. The increase in skin lipids found by Smedley-MacLean and Hume[4] in rats fed a fat-free diet was attributed to the synthesis of essential fatty acids by sebaceous glands[9]. According to the observations recorded here, the epidermis is the only site of lipid accumulation in the skin. By definition, essential fatty acids cannot be synthesized in the skin since these fatty acids are a dietary requirement of the animal. It is more likely that this fat is stored in the skin, and that the skin acts as a reservoir for the essential fatty acids sufficient to keep the animals alive. The increase in the thickness of the epidermis can be due to either or both the following two factors: (1) an increase in the mitotic activity of the basal layer;

(2) a decrease in the rate at which the epidermal cells keratinize. Since there is no significant increase in the mitotic activity of the basal cells[10], it seems more probable that the epidermal cells of mice deficient in fatty acid are retarded in their rate of keratinization by their involvement.

I thank Dr. Richard A. Ellis of Brown University and Dr. William Montagna of the Oregon Regional Primate Research Center for their advice, and Dr. Elizabeth Leduc of Brown University for providing the animals. Influence of Basic Antibiotics on Serum- and Liver-cholesterol Concentrations in Chicks

It has been reported[1] that orally administered neomycin lowers the serum-cholesterol level in man, and these results were confirmed in other studies[2-4]. Neamine and kanamycin have only a moderate effect, whereas streptomycin and dihydrostreptomycin are inactive[3,4].

As neomycin is very poorly absorbed from the gut, its action is probably restricted to the intestinal lumen. The modifications of the intestinal flora, induced by the antibiotic, are generally considered to be responsible for the cholesterol-lowering effect of this drug. Nevertheless, the observation that streptomycin, a substance with a closely related antibiotic spectrum, has no influence on serum-cholesterol concentration casts some doubt on this explanation.

An incidental observation that neomycin precipitates solutions of bile acids led us to suppose that the activity of this product might be due to its ability to form salts which interfere with the absorption of lipids from the intestine.

To examine this hypothesis, we have prepared and tested two types of neomycin derivatives which are devoid of antibiotic activity: *N*-methylated neomycin (Vanderhaeghe and Claes, unpublished work), which is basic, and *N*-acetylated neomycin[5], which is a neutral substance.

Five groups of 15 neonatal broiler chicks were fed a basic casein-sucrose diet containing 6 per cent corn-oil as the sole source of fat[6]. To this basic diet were added 0·2 per cent cholesterol and 0·15 per cent of the different substances under investigation, as indicated in Table 1. The experimental diets were fed for 2 weeks. After fasting overnight, the birds were bled by cardiac puncture and the serum- and liver-cholesterol concentrations were determined by the method of Abell *et al.*[7]. Fæcal fat excretion was determined daily according to Van de Kamer *et al.*[8].

As shown in Table 1, feeding 0·15 per cent neomycin or 0·15 per cent methylated neomycin reduced serum-cholesterol concentrations by 26 per cent and 17 per cent respectively. The *N*-acetylated neomycin was ineffective, and streptomycin rather tended to increase cholesterol levels. Table 1 also shows that the administration of neomycin or methylated neomycin resulted in an increased fæcal fat excretion; streptomycin and *N*-acetylated neomycin had no such effect.

Table 1. Effect of Neomycin, Streptomycin, and Two Neomycin Derivatives on Serum- and Liver-cholesterol and on Fæcal Fat Excretion in Chicks

	—	Neomycin 0·15 %	Strepto-mycin 0·15 %	Methyl-neomycin 0·15 %	*N*-acetyl. neomycin 0·15 %
Average serum-cholesterol, (mg/100 ml.)	267	198	284	222	270
Average total liver-cholesterol, (mg/100 g liver)	762	502	771	589	765
Fæcal fat, (mg/g dried fæces)	57	104	49	92	52
Body weight (g)	143	127	148	140	141

Our results indicate that the cholesterol-lowering effect of neomycin is due not to its antimicrobial activity but to the presence of basic groups in the molecule. This hypothesis could also explain the results obtained in human experiments by Samuel and Waithe[4]. Streptomycin, which does not lower serum-cholesterol, has only three basic groups. Kanamycin and neamine, with four amino groups, present a weak activity. Neomycin, an antibiotic with six amino groups, is the most active of the four drugs.

Further experiments in this laboratory have shown that both neomycin and methylated neomycin, but neither streptomycin nor acetylated neomycin, can break emulsions stabilized by lecithin (to be published). A similar effect on the emulsification of lipids in the intestine could explain the increase in fæcal fat output observed in the present work.

During these studies it was also found that neomycin and methylated neomycin when added to human or to chick bile cause precipitation of bile acids and phospholipids, and a correlation was observed between the bile-acid-precipitating activity of different compounds and their effect on the serum-cholesterol level in chicks. Moreover, feeding chicks with 0·25–0·5 per cent of methylated neomycin caused a five-fold to ten-fold increase in the excretion of fæcal bile acids, and addition of neomycin or methylated neomycin to a diet containing lithocholic acid protected chicks from the hepatotoxic effects of lithocholic acid[9], thus indicating interference with the absorption of bile acids from the intestine.

These experiments support the hypothesis that basic substances such as neomycin and methylated neomycin interfere with the intestinal absorption of fats, cholesterol, and bile acids by disturbing the emulsification of lipids in the intestine or by complexing bile acids. The cholesterol-lowering effect could then be explained by an impaired intestinal absorption of cholesterol and an increased degradation of cholesterol to bile acids in the liver.

Shrinkage Temperature of Eye Collagen

During a study of the shrinkage temperature of skin collagen, normal human eye collagen was included in the control material. A measure of difference was found between the sclera, which behaved as ordinary mammalian collagen[1–5], and the cornea, which showed a lower hydrothermal stability, in the sense that it shortened at a lower temperature than sclera or skin collagen.

Although the structure of the transparent cornea is well documented[6,7], and descriptions exist of the analytical differences between it and the sclera[8], there seems to be no ready reference to a lower shrinkage temperature.

Using a modified Theis apparatus[9] the results were as shown in Table 1.

Table 1

Specimen	Human eye	Sex	Age	Shrinkage temperature (° C) 55	56	57	58	59	60	61	62	63	64	65
314	Normal cornea	F	66				1							
314	Normal sclera	F	66								1			
318	Normal cornea	M	84			1								
318	Normal sclera	M	84								1			
321	Normal cornea	F	81			1								
321	Normal sclera	F	81								1			
323	Normal cornea	M	62		1									
323	Normal sclera	M	62								1			
324	Normal cornea	M		1										
324	Normal sclera	M									1			
325	Normal cornea	F	60			1								
325	Normal sclera	F	60									1		
330	Normal cornea	M	18								1 } Astro-			
330	Normal sclera	M	18								1 } cytoma			
333	Normal cornea	M		1										
333	Normal sclera	M										1		
291	Normal cornea	M					1							
272	Normal cornea	F	86		1									
STB1	Normal cornea	M	69	1										
STB2	Normal cornea	M	58				1							
STB3	Normal cornea	F	82	1										
STB3	Normal sclera	F	82							1				
STB4	Normal cornea	M	65				1							
STB4	Normal sclera	M	65							1				

These findings relate only to the translucent area of normal eyes; investigation of pathological specimens is pending.

Biochemical Chlorination of *Streptomyces aureofaciens*

Earlier work on the chlorination mechanism of *Streptomyces aureofaciens* established that chlorine of chlorinated fatty acids was incorporated into the molecule of 7-chlorotetracycline (CTC)[1,2].

Recently, Sekizawa has found that the chlorine of chlorpropanediols was also incorporated into CTC and, moreover, this compound was able to overcome the effect of known chlorination inhibitors[3–5]. Sekizawa also reported that after the addition of chlorpropanediols to the media of oxytetracycline-producing strains, CTC could be detected[6]. He therefore supposed chlorpropanediols to enter directly into the tetracycline (TC) molecule during the course of biosynthesis preceding the chlorination reaction.

The conditions of chlorine incorporation were investigated by the application of $Na^{36}Cl$, using 2,5-dimercaptothiadiazole[1,3,4] as chlorination inhibitor. Regarding organic chloro-compounds, the incorporation of chlorine from 1-^{14}C-acetate (MCA), 2-^{14}C-MCA and 3-chlorpropanediol[1,2] was investigated. Incorporation of the carbon of monochloracetates into TC was also detected.

Strains of CTC-producing *Str. aureofaciens* 'B-28' (ref. 7) and the tetracycline producer *Str. aureofaciens* 'CDSD-314' (ref. 8) were used for the present experiments. The synthetic medium and experimental conditions were the same as reported earlier[7,9].

Using isotopically labelled NaCl it was shown that TDA exerts its inhibitory action in the first oxidative stage of chlorination. $Na^{36}Cl$ could be detected in the broth of chlortetracycline fermentations inhibited by TDA. Similarly, chloride could be detected about the end of fermentations of TC-producing 'CDSD-314' strain. These facts support the assumption that inhibition of chlorination was effected in the first phase of the biosynthetic chain, genetically manifest during the course of strain production[8]. But, in contrast to the inhibition of TDA, in the case of strain 'CDSD-314' copper did not suspend the inhibition of CTC production; the genetic block has been found to be irreversible (Table 1).

Table 1 shows that, in the case of *Streptomyces aureofaciens* 'CDSD-314', the 'residual reaction' supposed by Sekizawa[6] to be general in chlorination reactions could not be found. In our opinion the appearance of a 'residual reaction' in the case of predominantly TC-producing strains depends on the localization of the genetic block. We suppose, however, that at the very first stage of chlorination there is no alternative pathway in the biogenesis of CTC; later, there may be a partial separation of the reaction routes.

By the use of 1-^{14}C-MCA and 2-^{14}C-MCA it could be shown that, in the case of strain 'B-28', the chlorine of MCA, decomposed enzymatically, was incorporated into the CTC molecule. It was found that TDA did not inhibit the incorporation of carbon from MCA 1-C and 2-C into the tetracycline molecule. Similarly, in the case of strain 'CDSD-314', independently from the genetic block, carbon atoms of MCA were incorporated into TC (Table 2). We suppose that the first step of chlorine utilization is an enzymatic cleavage of the chlorine of MCA to inorganic chloride during the metabolism of both strains. Afterwards, evidently, chloride will be incorporated into CTC only in the case of the CTC-producing strain 'B-28'.

The possibility reported by Sekizawa that propanediole may be a direct precursor for CTC would have been confirmed if the production of CTC could have been detected at the end of the fermentation, after giving chlorpropanediole to the culture of the exclusively TC-producing strain 'CDSD-314'.

Experimental results obtained in our laboratory did not support the assumption of Sekizawa. CTC could not be detected in the fermentation broth of strain 'CDSD-314', thus excluding the possibility that chlorpropanediol acts as a direct precursor of CTC, if it is assumed that, in general, the biosynthesis is similar in TC- and CTC-producing

Table 1

Strain	Materials*	Total antib. activity mcg/ml.	Breaking per mg of antibiotics	CTC (%)*	Chloride det. at the end of fermentation
B-28	—	1,080	1,512	100	32
B-28	0·2 mM TDA	1,040	396	26	80
B-28	0·2 mM TDA + 0·3 mM $CuSO_4$	825	1,180	74	38
CDSD-314	—	1,370	38	0	98
CDSD-314	0·2 mM TDA	1,280	32	0	96
CDSD-314	0·2 mM TDA + 0·2 mM $CuSO_4$	1,010	36	0	99
—	—	—	40†	—	96

* As an isotope source 0·4 μc./90 ml., $Na^{36}Cl$ was added at 0 h for each experiment.
† Activity was related to an equal quantity of butanolic extract. The small activity observed in the control flask may be due to a small amount of ^{36}Cl dissolved in butanol.

Table 2. Incorporation of the Carbons of 1-^{14}C-MCA and 2-^{14}C-MCA into CTC – TC Molecules

Strain	Materials	Total antibiotic activity * mcg/ml.	Breaking in relation to 1 mg CTC + TC
B-28	2-^{14}C-MCA *	1,050	3,170
CDSD-314	2-^{14}C-MCA	1,170	3,470
B-28	2-^{14}C-MCA + 0·2 mM TDA	1,030	2,970
CDSD-314	2-^{14}C-MCA + 0·2 mM TDA	1,200	3,380
B-28	1-^{14}C-MCA	1,130	2,060
CDSD-314	1-^{14}C-MCA	1,330	2,190
B-28	1-^{14}C-MCA + 0·2 mM TDA	1,180	2,110
CDSD-314	1-^{14}C-MCA + 0·2 mM TDA	1,310	2,120

* Monochloracetates (MCA) were used in 1 μc./80 ml. concentration.

Table 3. Effect of Chlorpropanediol on the Biosynthesis of CTC in Cultures of CTC-producing and Non-producing Strains

Strain	Time of addition	Materials added	Fermented CTC + TC mcg/ml.	CTC (%)	Appearance of chloride at the end of fermentation
B-28	—	—	1,140	2	–
B-28	0	4 mg/ml. chlorpropanediol	870	100	+
B-28	0	4 mg/ml. chlorpropanediol + 0·2 mM TDA	1,070	37	+
B-28	24	4 mg/ml. chlorpropanediol	790	85	+
CDSD-314	—	—	1,490	0	–
CDSD-314	0	4 mg/ml. chlorpropanediol	960	0	+
CDSD-314	0	4 mg/ml. chlorpropanediol + 0·2 mM TDA	1,030	0	+
CDSD-314	24	4 mg/ml. chlorpropanediol	760	0	+

micro-organisms. However, by the sensitive radioactive test it was possible to detect inorganic chloride at the end of TC fermentations (supplied with chlorpropanediol), thus furnishing evidence that decomposition of chlorpropanediol takes place during the course of fermentation. This fact strongly supports the evidence that in the case of strain 'B-28' inorganic chloride originated from an enzymatic decomposition of chlorpropanediol was incorporated into CTC, as in the case of chloracetates (Table 3).

After our experiments had been completed[10], it was reported by Goodman *et al.* that the reversing effect of chlorpropanediols on chlorination inhibitors can be explained by the alkylation of the inhibitors[11]; in their roles as chlorine sources in the metabolism of CTC-producing micro-organisms a close parallelism can be drawn between chlorpropanediols and chlorinated fatty acids.

From the results of our experiments we suppose that at least two stages can be distinguished at the early phase of chlorination. Presumably the first step is the oxidation of chloride to chlorinium ion, as was reported by Shaw *et al.* in the case of *Cald. fumago*[12]. A reaction of chlorinium ion with a common intermediary of TC and CTC may represent the second step. At present we have no exact idea about the nature of this intermediate, but it may be pretetramide (1,3,10,11,12-pentahydroxy-naphthacene-2 carboxamide), which is an intermediate in the formation of 6-demethyl-CTC as shown by the recent excellent work of McCormick *et al.*[13]. Presumably TDA inhibition extends only to the first oxidative step and is ineffective. The genetic block of strain 'CDSD-314' naturally can be spread over both steps, but exact elucidation of this question requires further experiments.

Auxin and Gibberellin-like Substances in Peanut (*Arachis hypogaea*)

The results here presented are part of an investigation on dormancy in seeds of the peanut, variety 'Virginia Bunch'. This variety requires 'after ripening' in dry storage for about 4 months in natural conditions in Israel.

While experimenting with the dormant seeds in order to find a practical method of overcoming dormancy in the laboratory, it was found that seeds (intact and naked), leached overnight at about 25° C, will germinate satisfactorily. Keeping in mind that inhibitors may be leached out, we carried on experiments with the leachates.

Leachates in several concentrations could not prevent germination, but slowed it down and inhibited radicle growth of seedlings, as well as cress-root growth. As no significant difference could be found between dormant and non-dormant seed, more detailed examination of the leachates was made.

Wheat coleoptile section growth (variety 'Atle'), oat mesocotyl section growth (variety 'Victory') and cress-root bioassays were carried out after leachates had been freeze-dried, taken up in 80 per cent methanol and chromatographed in a descending solvent system consisting of isopropanol 1/100 × 0·88 sp. gr. ammonium hydroxide (4 : 1).

No clear results could be obtained with the coleoptile test. In the mesocotyl test, a growth promoter with a peak at R_F 0·2–0·3 was found and the cress-root test showed strong inhibition at about the same R_F. In the leachates from non-dormant seed, a somewhat higher growth-promoting activity was found in the last two bioassays, but no significant difference could be shown. These results suggest that an auxin-like substance is leached out, the R_F of which is lower than that of synthetic indolyl-3-acetic acid (IAA) which was run as a marker. However, no direct relation could be shown between the observed growth promotion and seed dormancy, nor could a growth inhibitor be demonstrated by these methods. The next step was an examination of the growth substances of the seeds themselves.

Seeds were crushed by means of mortar and pestle and extracted with 80 per cent methanol for 24 h at 0° C. The methanol was changed once after 22 h. The combined methanol extract was distilled under vacuum at 30°–35° C and the aqueous residue was freeze-dried. The dry residue was then dissolved in a small volume of 80 per cent methanol ('crude extract'). For chromatographic separation, the same solvent and the same bioassay as with the leachates were used. The equivalent of 5 g dry weight of seed was used for each bioassay.

With the wheat coleoptile section test, again no significant differences were obtained. When the oat mesocotyl test was used with dormant and non-dormant seed extracts, growth-promotion was found at R_F 0·3–0·6. IAA and gibberellic acid (GA) markers respectively corresponded with these R_Fs. In some cases, a second zone of activity was found at R_F 0·8–1·0 in the dormant seed extracts. Cress-root tests made on these extracts showed pronounced inhibition at R_F 0·2–0·4, followed by a very marked decrease in inhibitor. At R_F 0·8–1·0, a slight promotion was found in the dormant seed extract.

For gibberellin investigations, seeds were extracted as mentioned above. The procedure of purification was based on that of Radley[1] with slight modifications[2]. The 'pure' extract was then chromatographed on paper, using as a developing solvent isopropanol/ammonia (as described formerly), or *n*-butanol, saturated with 1/100 × 0·88 s.g. ammonium hydroxide.

Three bioassay techniques were used: (1) Dwarf-maize leaf section test, based on that of Boyarkin and Dmitrieva[3], using dwarf-1 mutant instead of normal maize. (2) Lettuce hypocotyl test[4] with the 'Gotte-A-Forcer' variety. (3) Oat mesocotyl test.

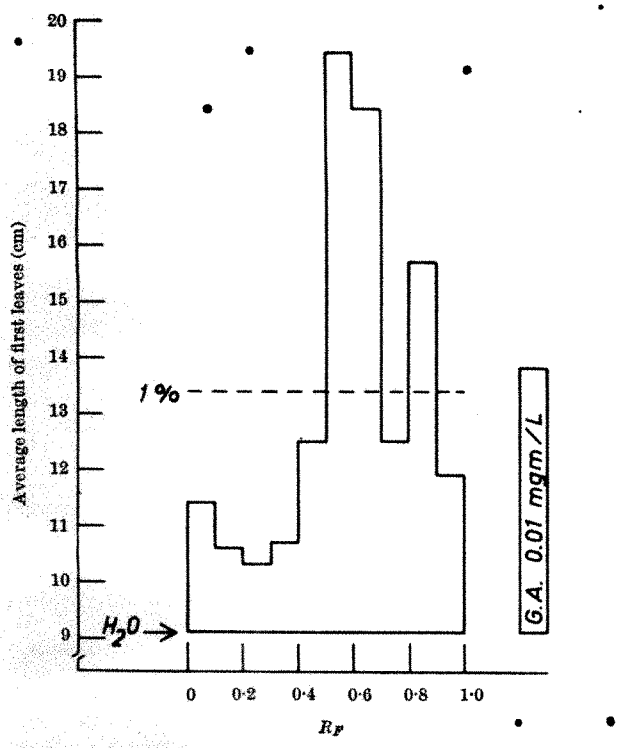

Fig. 1. Maize leaf section bioassay of purified extracts of dormant seed. Ordinates indicate the final length of first leaves. Broken line indicates 1 per cent level of significance

The equivalent of 50 g was used for the bioassays Nos. 1–2 and of 5 g for No. 3. The results obtained suggested the existence of a gibberellin-like promoter in both dormant and non-dormant seed extracts. (When isopropanol/ammonia was used as the solvent system, a peak occurred at R_F 0·5–0·6, and with *n*-butanol/ammonia, a peak was found at R_F 0·2–0·3.)

In dormant seed extracts another zone of promotion occurred. Its R_F (0·8–1·0) with the maize leaf and oat mesocotyl assays corresponded to that obtained with the mesocotyl test on 'crude' extracts of dormant seed (Fig. 1). In our isopropanol/ammonia solvent, IAN occurs at about R_F 0·9. When several concentrations (0·01, 0·1, 1 p.p.m.) of β-indolylacetonitrile (IAN) were used in the dwarf-maize test, no promotion was obtained. These results would suggest that IAN is not responsible for the activity found in dormant seed extracts at R_F 0·8–1·0. The fact that in a cress-root test of the dormant extract a slight promotion was found in the above R_F, while with IAN an inhibition would be expected, may be further evidence for this assumption.

The results of the bioassays with extracted seeds suggest, therefore, that auxin and gibberellin-like substances are found in dormant and non-dormant peanut seeds. In the isopropanol/ammonium hydroxide solvent, IAA appears at about R_F 0·4, GA at R_F 0·5–0·6, and in the dormant seed a second promoting zone is found at R_F 0·8–1·0.

Koshimizu *et al.*[5] obtained in bamboo shoots gibberellin-like substances with R_F values of 0·8–1·0 in the solvent system isopropanol/water (4 : 1). They state that the activity on the *d*-1 maize mutant was very low compared with that on the *d*-3 and *d*-5 mutants. In our dormant seed extract we could get very pronounced promotion with the *d*-1 mutant in the maize leaf section test, but we did not try other mutants for relative activity.

The nearest R_F to that stated here for a known gibberellin is that of gibberellin A_9 which runs at R_F 0·77 in isopropanol/water 4 : 1 (ref. 6). From an investigation on relative activity of the gibberellins[7] it is known that the activity of A_9 on the *d*-1 mutant is practically nil. This fact and the difference in R_F values suggest that the promoting substance found in the dormant peanut seed extract is not gibberellin A_9.

Whether this promoter has any bearing on dormancy and after-ripening in peanut seed should be examined by further investigations.

The experiments described here were carried out while one of us (A. G.-S.) was the holder of a British Council Scholarship.

PHYSIOLOGY

Effect of Locally Applied Hemicholinium on the Acetylcholine Content of the Caudate Nucleus

ALPHA, alpha-dimethylethanolamino-4, 4′-biacetophenone (hemicholinium-3 or HC-3) is known to inhibit acetylcholine synthesis both in peripheral structures[1] and in the brain[2]. Since it causes death from respiratory failure when given parenterally, detailed investigations of its actions have so far been confined to isolated, perfused structures such as the superior cervical ganglion, while its effects on brain centres, like the caudate nucleus, which have the ability to synthesize acetylcholine at a high rate, have not been analysed. In this report we describe experiments in which we have observed the effects of HC-3, injected directly into the caudate nucleus of the rat, on the acetylcholine content of the nucleus, and on its ability to convert radioactive choline to acetylcholine.

Cannulæ (internal diam. 0·5 mm) were implanted by methods previously described[3] in the caudate nuclei of rats weighing 250 g under stereotaxic guidance and six days allowed for recovery from the operation. 3–5 μl. of saline, 3 μl. of HC-3 (3·6 μg/μl.), or 5 μl. of choline methyl-^{14}C (specific activity 3·6 mc./m.mole, concentration 7·8 μg/μl.), alone or in succession, were injected into the cannulæ from a μl. syringe, and, after appropriate intervals, the animals were killed by lightly anæsthetizing with pentobarbital and slitting the large vessels of the neck.

The head of each nucleus was immediately removed and its acetylcholine extracted in acid ethanol by a modification of the method of Crossland[4]. If the extracts were to be assayed for dopamine, a known quantity of tritiated noradrenaline (specific activity 7·59 c./m.mole) was added to permit estimation of recovery. The total volume of extractant and water used for washing was 4 ml. for each nucleus, on average 40 mg in weight. To this 1 drop of B.D.H. indicator was added, the solution brought to *p*H 4 with 0·2 N NaOH, and the volume then reduced to 0·5 ml. by blowing air over it while it was kept at 40°–50° C.

Chromatography. Extracts to be asayed for radioactive acetylcholine were spotted at this stage on Whatman No. 1 chromatographic paper. Descending chromatograms were run in *n*-propanol–formic acid–water (8 : 1 : 1) for 24 h. The solvent was allowed to run off the end so that acetylcholine achieved an apparent R_F of 0·90 and choline 0·74. A third, unidentified, radioactive spot always appeared at R_F 0·24. No other radioactive area was found. Acetyl-

choline and choline were located by adding cold carrier to the extracts and spraying duplicate chromatograms with Dragendorf's reagent. Areas on the unsprayed chromatogram corresponding to acetylcholine and choline were cut out, placed in vials with liquid scintillation phosphor, and counted in a liquid scintillation spectrometer[5]. The presence of acetylcholine was proved by combining eluants from the appropriate areas of several chromatograms, adding acetylcholine bromide and recrystallizing to constant specific activity from alcohol–ether.

Assay. Extracts to be assayed on a leech strip were diluted with 2 ml. of leech Ringer's solution; 2 drops of 0·4 N $HClO_4$, which produced a considerable precipitate, were then added. The precipitate was discarded, and the neutralized extract made up with leech Ringer to 5 ml. for assay.

The assay was conducted on a 2 mm × 30 mm eserinized strip of the dorsal muscle of *Hirudo medicinalis*. In all cases, the activity assayed as acetylcholine was shown to disappear on treatment with alkali (N NaOH). In most cases, the activity was matched against standard acetylcholine solutions to which an equivalent amount of neutralized alkali-treated extract was added. A few of the extracts shown to be active on eserinized leech muscle were tested on uneserinized preparations and found to have no apparent activity. Extracts of tissue to which HC-3 had been added sometimes depressed the leech muscle and the assays were then repeated on fresh muscle. With a good strip, however, standard acetylcholine solutions to which the appropriate amount of HC-3 was added, as well as caudates to which HC-3 was added at the commencement of the extraction, yielded the values to be expected in the absence of HC-3. In some preparations, HC-3 itself caused a slow contraction of the leech muscle. Such effects were controlled by assay against the usual combination of alkali-treated extract with acetylcholine as well as assay against acetylcholine solutions to which appropriate amounts of HC-3 were added.

About half the extract was treated with alumina at alkaline *p*H, the alumina eluted with 1·5 ml. of 0·5 N acetic acid and the eluant analysed for dopamine[6]. An aliquot of the final column eluant was then counted in a liquid scintillation spectrometer to determine the recovery of tritiated noradrenaline; recoveries averaged about 90 per cent when corrected for the aliquot of extract used in this procedure.

Measurements made on a control series of 12 animals, of which 5 had no operation, 3 had a cannula implanted in one caudate, and 4 had cannulæ in both caudates, established that whether cannulæ had been implanted or not, and whether in one or both nuclei, the acetylcholine concentration of the two caudates of the same animal did not differ from each other by more than 15 per cent, which is within the assay error, and usually by less than 10 per cent. For the 12 control animals the range of values expressed as μg/g tissue for the right and left nuclei was from 3·3 and 3·2 respectively in one animal to 7·4 and 8·6 in another. The mean of the total of 24 values was 4·9 ± 1·27 (*S.D.*).

It can be seen from Table 1 that HC-3 injected into one or other nucleus has a great effect on its acetylcholine content and reduces it significantly within a few minutes. The response to the drug varied somewhat from rat to rat, so that a smooth time curve was not obtained.

The values for dopamine in Table 1 showed considerably more variation than those for acetylcholine, but there was clearly no consistent change due to the HC-3. This would indicate that the effect on acetylcholine content is not due to non-specific destruction or inhibition of the metabolism of the caudate cells.

Preliminary results on the *in vivo* synthesis of acetylcholine from radioactive choline shown in Table 2 are a further indication that the effect of HC-3 is due to inhibition of acetylcholine synthesis.

Table 1. Effect of 3 μl. of HC-3 injected into one caudate nucleus

Time of death after injection of HC-3	Conc. ACh μg/g tissue Control	Test	Test as % of control	Dopamine μg/g tissue Control	Test	Test as % of control

Table 2. Conversion of choline-^{14}C to ACh-^{14}C in caudate nucleus

Time from HC-3 injection to choline-^{14}C inj.	Time from choline-^{14}C injection to death	$\frac{\text{ACh-}^{14}\text{C}}{\text{Choline-}^{14}\text{C}} \times 1{,}000$ HC-3 caudate	Contralateral caudate
1 h	0·5 h	11	34
1 h	1 h	20	44

$\frac{\text{ACh-}^{14}\text{C}}{\text{Choline-}^{14}\text{C}}$ is ratio of counts per min in the two fractions isolated by paper chromatography.

In these experiments, HC-3 was injected into one caudate, and 1 h later choline–methyl-^{14}C was injected simultaneously into both caudates. The effect of the HC-3 was judged by comparing the ratio of acetylcholine–^{14}C to choline–^{14}C in the caudate receiving HC-3 with that in the control caudate. The results show more net synthesis of acetylcholine 1 h after choline–^{14}C than after 0·5 h, and in each case the acetylcholine synthesis was considerably less on the HC-3 side.

Only about 5 per cent of the injected radioactivity was recovered, and only 1–2 per cent of this was as acetylcholine. Choline and the unidentified spot accounted for most of the radioactivity recovered.

The lowest values for acetylcholine in the treated nucleus were 8–12 per cent of the control nucleus. Since this appears to be the minimum level to which the acetylcholine could be reduced by HC-3, the balance of 88–92 per cent may be taken to correspond to the depot acetylcholine of the caudate nucleus as defined by Birks and MacIntosh[7] for the superior cervical ganglion. In the case of the ganglion, this fraction is about 85 per cent of the total acetylcholine. In the case of pons and medulla in the investigation by Metz[2] where HC-3 was given intravenously in minimal doses, the acetylcholine content fell to 4–25 per cent of the control levels during severe depression and respiratory failure. There is, therefore, a reasonable measure of agreement in the dimensions of the response of these various tissues.

The values observed after 24 h and later indicate that the HC-3 effect is reversible, though probably rather slowly so. The variation in response, which is most obvious in the very different values found for the two animals tested 15 min after HC-3, may reflect efficiency of diffusion, individual susceptibility to the drug, or the state of activity in the nucleus. If it is accepted that the reduction of acetylcholine is due to the effect of HC-3 on synthesis only, possibly indirectly by filling up storage spaces, it follows that the rate at which the drug reduces the level of stored acetylcholine will depend on how fast the pre-existing acetylcholine is being released. In these experiments it appears that it required a minimum of 10 min to discharge 50 per cent of the acetylcholine, but this time includes that required for diffusion and penetration of the drug. The true turnover time for acetylcholine in the caudate is therefore probably much less than the 20 min indicated by these experiments. The situation may be analogous to that encountered by Birks and MacIntosh[1,7] in the perfused superior cervical ganglion. In an untreated ganglion the resting content of acetylcholine could be turned over with about 10 min of stimulation, but more than 20 min of stimulation was required to reduce the acetylcholine to the minimal level in a ganglion treated

with HC-3. The difference in time presumably represents the time required for HC-3 to achieve its full effect in this system.

The results on synthesis of radioactive acetylcholine are only preliminary since little is known about how most of the injected choline was metabolized. Alcohol extracts of blood and the various organs showed heavy labelling, indicating wide distribution of the radioactivity. Radioactivity was also detected in the precipitate from the acetylcholine extraction, suggesting the possibility that some injected choline was incorporated into brain lipids. With several routes competing for the injected choline, and with the possibility of HC-3 influencing any of them, there must be some doubt that the influence of HC-3 on the radioactive acetylcholine/choline ratio is solely due to interference with acetylcholine synthesis.

Approximately 0·03–0·06 μg of radioactive acetylcholine were detected, indicating a net synthesis rate of 1–2 μg/g/h. Considering that diffusion of the choline-^{14}C and mixing with the cold pool had to take place before radioactive acetylcholine synthesis, and that breakdown of the synthesized radioactive acetylcholine was undoubtedly taking place *in vivo* before death, the observed net radioactive synthesis rate is obviously far below the true endogenous synthetic rate. A rate closer to 30 μg/g/h would be indicated by the HC-3 experiments, but again this is probably low. The acetylcholine-synthesizing capacity of the caudate of the rat, as indicated by the choline acetylase activity *in vitro*, is of the order of 8,000–10,000 μg/g tissue/h (ref. 8). Ordinarily, synthesizing enzymes are present in generous excess, so that this figure is undoubtedly far above the true rate. Even so, it is probable that our experiments with radioactive choline grossly underestimate the turnover rate of ACh in this tissue. Their positive value is that they provide further evidence that HC-3 interferes with ACh synthesis *in vivo*.

We thank Profs. F. C. MacIntosh and F. Schueler for gifts of samples of HC-3.

The cost of this research was defrayed by grants from the Medical Research Council of Canada (to C. O. H. as visiting scientist), a Canadian Federal Provincial Mental Health Grant (609–5–141) and the U.S. National Science Foundation (*GB*–827).

Thermogenesis and Thyroid Action

FOR some time[1,2] it has been realized that thyroid hormone raises metabolic rates, increases activity of the hexose monophosphate pathway, decreases apparent TPNH–DPN transhydrogenase activity and stimulates 5 α-steroid reductase activity. More recently thyroxin has been shown to increase by a factor of ten or twenty the activity of the intra-mitochondrial α-glycerophosphate dehydrogenase with no concurrent effect on the 'soluble' counterpart[3,4].

The net result of the latter action is to drive the reduction of dihydroxyacetone phosphate (DHAP) toward alpha-glycerophosphate (α-G-P) by a DPNH-requiring enzyme in the extra-mitochondrial phase, and conversely to facilitate the reverse reaction within the mitochondrial compartment, wherein the oxidation of α-G-P is coupled to cytochrome *c*; the resultant is to give rise to only one phosphorylation during the course of transfer of energy from DPNH to acceptor, with the formation of water. Thus we retain in the potential energy pool the energy equivalent to only one high-energy phosphate bond (~P). This is in contrast to the usual electron transport sequence by which intra-mitochondrial oxidation of beta-hydroxybutyrate, for example, passes through DPNH to water with formation of 3~P.

Hence the latter reaction gives three times the work function that is derived from oxidation of α-G-P, and in lieu of data to the contrary one must conclude that the DPNH oxidation via the α-G-P pathway proceeds at one-third the efficiency of that via the full complement of the electron transport chain. Thus it follows also that this pathway must yield heat in an amount equivalent to at least two of the phosphorylative steps normally associated with the electron transport chain.

In view of the differential stimulatory effect of thyroxine on the α-G-P 'shuttle' as described above, it is proposed that possibly the major thermogenic effect of that hormone is mediated through preferential use of this pathway. This would not be inconsistent with the fact that 3-phospho-glyceraldehyde is an important end product of the thyroid-stimulated hexose monophosphate pathway (HMP) and that extra-mitochondrial equilibrium conditions heavily favour the reduction of DHAP to α-G-P (ref. 5).

This proposal also implies that DPNH of the extra-mitochondrial phase is not directly transferred into the mitochondrion, but rather that its hydrogen is transported by small, readily diffusible components such as α-G-P and β-hydroxybutyrate. Documentation in support of this dates from earlier work[6] showing that DPNH is not readily transferred into the intact mitochondrion *in vitro*, though it may be depleted from these sites by treatments which probably increase the normal permeability of the confining lattice[7].

The extent to which thyroid activity directs triose phosphate into the α-G-P shuttle would appear to influence adversely the synthesis of fats relative to their degradation. According to the line of reasoning outlined, this influence would, in effect, favour the α-G-P pathway over that of β-hydroxybutyrate, with correspondingly greater oxidation relative to phosphorylation, that is, with greater heat production relative to work potential.

The net thermogenic resultant of TPNH generation by HMP activation appears both in non-phosphorylating extra-mitochondrial pathways, coupling probably through cytochrome b_5 with molecular oxygen[2], and also in the extent to which rising levels of TPNH in liver of rats[8] appear during cold-acclimation along with the microsomal TPNH cytochrome *c*-reductase[9,10]. In thyroxinized rats the latter rises as both the DPNH cytochrome *c*-reductase and total DPN fall[10–12] with increasing dosage levels. As no uncoupling of mitochondrial oxidative phosphorylation occurs during such treatment unless microsomal elements are also present[2,10,11], it is concluded[2] that apparent 'uncoupling' (reduction of P/O ratio) in the latter instance implies a shunting of oxidative activity via extra-mitochondrial, poorly phosphorylative pathways, with attending thermogenesis.

Finally, the normal reductive distribution of H via TPNH into the fat depots leaves open the relative thermogenic contribution of the respective degradative pathways

of the fatty acids. Considering only initial and final states between TPNH and H_2O, it is clear that thermogenesis will vary as the work function (potential energy pool) generated along the oxidative pathway. Hence, excluding that portion metabolized via mitochondrial DPNH-dependent pathways, the more thermogenic routes will be those passing by way of the acyl dehydrogenases to the electron transport flavins (ETF) (ref. 13); the latter, coupling through FAD, will exhibit phosphorylative ratios (P/O) of the order of 2, that is, a work function of 2/3 of that of β-hydroxybutyrate and thus thermogenesis in equivalence of $1 \sim P$.

Whether additional thermogenesis is derived through subsequent utilization of the potential energy ('high-energy') bond pool formed in these reactions is essentially irrelevant to the present argument, since the thermal yield from this source will depend on the efficiency of the mechano-chemical or other coupling and the external work performed by the system. It is, of course, acknowledged that in all transfers, both to and from the potential energy pool, heat losses (thermogenesis) may also be expected, so that in this sense total thermogenesis tends to increase as a function of turnover rate whatever the pathways used.

It is concluded, therefore, that thermogenesis from thyroid action is facilitated by recourse not to uncoupling of mitochondrial oxidative phosphorylation, but rather by emphasis of alternative pathways wherein both DPNH and TPNH are oxidized either by extra-mitochondrial, poorly phosphorylating transfers, or by indirect couplings at lower potential levels of the electron transport chain. Important mediators of this appear as the α-G-P shuttle and a quasi-trans-hydrogenation via the fat depots[14] and the acyl dehydrogenases.

Trigeminus Reflex in Young Infants

A weak electrical stimulus on the receptive field of N. trigeminus (parts II and III) in infants between a few weeks and 12 months old is followed by a discharge in the nerves of the muscles, biceps and triceps brachii, and biceps and quadriceps femori, without any visible movement. The activity of these muscles is synchronized. No reciprocal pattern could be detected. We found two groups of latencies—one with a maximum at 140 msec and a second between 300 and 400 msec (Fig. 1). Stimulation of regions other than that supplied by the trigeminal nerve is without effect, unless the stimulus is very strong —a fact which is in accordance with the work of Hooker[1] on human fœtuses. We suppose that the myographically-

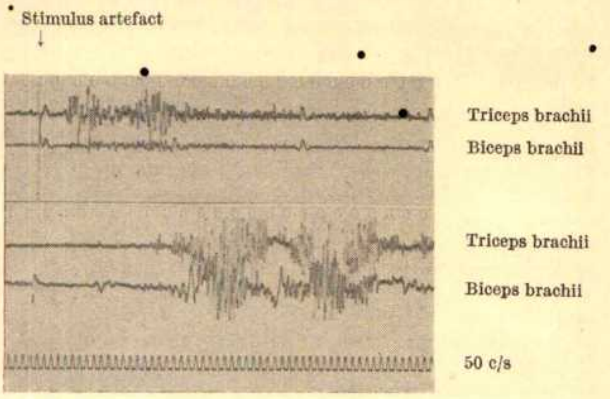

Fig. 1

tested reactions of muscles of the extremities have nothing to do with the Moro-reflex, or common fright reaction, which is often seen after very strong visual, acoustic or tactile stimulation.

Potassium-free Effect in Squid Axons

Previous work[1] has shown that the sodium efflux from squid giant axons is sensitive to the external concentration of potassium ions; the Na efflux falls to about 1/3 of control values when the sea water surrounding the axon is made free from potassium. Similar observations have been made with frog sartorius muscle[2], but these showed further that when $[Na]_i$ in muscle was low, Na efflux was no longer sensitive to external [K]. The following experiments were undertaken to see if the Na efflux from squid axons would be similarly insensitive to $[K_0]$ if $[Na]_i$ were low.

Preliminary trials showed that two different methods yielded giant axons with a low $[Na]_i$. In the first, axons were immersed for 6 h in 400 mM KCl + 50 mM $CaCl_2$ solution with the *p*H adjusted to 8·0 with *tris*. Such axons had, on analysis, $[Na]_i$ of about 35 mM. In a second method, axons were stimulated in normal sea water with all Na^+ replaced by Li^+ for 0·5 h at 60/sec. An analysis of the axoplasm of 7 axons subjected to stimulation in Li-sea water showed the following mean values: $[Na]_i = 36$, $[K]_i = 158$, $[Li]_i = 117$ m.mole/l. Other (unpublished) measurements from our laboratory for fresh axoplasm showed a value for $[Na]_i$ of about 70 mM so that both experimental treatments reduced $[Na]_i$ to about half that of fresh axoplasm. Because the experimental procedures involved much time and axon survival was judged to be a critical factor in their success or failure, the stimulation in Li method was chosen for all the measurements to be reported. The $[Li]_i$ found above can be compared with an entry of Li of 43 μmole/g calculated on the basis of a resting influx of 50 pmole/cm²sec for the 3 h that the axon was isolated and using a factor of 80 cm^{-1} for the surface : volume ratio of a 500μ axon. To this must be added 69 μmole/g resulting from stimulation at 60/sec for 30 min and using a value of net Li flux of 6 pmole/cm² impulse as appropriate to a temperature of 10° C. The sum of the stimulated and resting entry yields a final $[Li]_i$ of 112 mM, which is quite close to the value obtained from analysis. It might

appear that the most direct method of obtaining axons with a low $[Na]_i$ is to use perfused axons with zero $[Na]_i$ in the perfusion fluid; such axons, however, have an unstable Na efflux and are not suitable for the measurements to be described.

Squid axons used in this work were dissected from *Loligo pealii* and the axon immersed in Li-sea water, where it was cleaned. The axon was then transferred to a 'Teflon' chamber, where it was stimulated in Li-sea water containing about 1 mM ^{24}NaCl. After stimulation, the axon was washed in several changes of Li-sea water and was finally left for 1·5 h in fresh Li-sea water. The axon was then mounted in a 'Teflon' chamber with a groove through which various fluids were circulated past the axon with a motor-driven syringe. The fluid coming from such a chamber was collected every 3–5 min and the samples dried in planchets, and these were monitored for radioactivity by counting under a flow-gas Geiger tube with anticoincidence guard. The sequence of external solution changes was generally: Li-sea water, K-free Li-sea water, and a return to Li-sea water. In some cases, measurements were made of the change in Na efflux when an axon with a normal $[Na]_i$ was transferred from Li-sea water to K-free Li-sea water, and, in other cases, axons were transferred to Na-sea water (K-free) at the end of a long experiment in Li-sea water. In some experiments, 'Vaseline' seals were used to keep the ends of an axon from coming into contact with radioactive loading and efflux solutions; in other experiments this technique was abandoned in favour of radioactive loading of an axon before cleaning and afterwards cutting off about 5 mm from each end of the axon after cleaning. As the results were not different with the two techniques, it was concluded that extensive washing of the axon clears sufficient radioactivity from the ends of the axon so that the measurement of Na efflux is not greatly in error. All axons used were tested for excitability throughout the experiments and axons were discarded if they became inexcitable. Axons were loaded with Li^+ at 10° C, but efflux was measured at 20° C.

The results obtained are summarized in Table 1. In going from Li-sea water to K-free Li-sea water there is no change in Na efflux, while in going back to Li-sea water there is a 6 per cent increase in efflux but this is not statistically significant. The changes in Na efflux are based on c.p.m.^{2} of Na efflux evaluated over sampling times of 3 or 5 min. At least 3 efflux samples (and more usually 5) were collected under each experimental condition. The loss of Na from a fibre as large as a squid axon is so slow that the concentration cannot be expected to change by more than 10 per cent over a sample collection period of 90 min. Efflux as c.p.m.^{2}, rather than rate constant of Na loss, has been used in these measurements. A clear change in Na efflux is evident, however, when the axon is transferred from Li- to Na-sea water; the Na efflux then increases by about 50 per cent over values in Li-sea water and this change is independent of whether the Na-sea water has K^+. This finding is also new because previous measurements of the effect of Na-free solutions on squid axons have shown that Na efflux decreases on going from Na-free to Na-containing sea water[1,3]. Axons No. 2 and 10 (with a normal $[Na]_i$) were loaded with ^{24}Na by stimulation for 5–10 min in Na-sea water and were washed for 1·5 h in Li-sea water. They were then tested for a K-free effect. For axon No. 2, Na efflux in K-free Li-sea water was found to be 0·5 that for Li-sea water, while axon No. 10 showed an efflux in K-free Li-sea water that was 0·4 that of Li-sea water. Both axons were afterwards stimulated in Li-sea water to reduce $[Na]_i$, and the further results with these axons are shown in Table 1.

The results of this investigation may be summarized by saying that when the internal Na concentration of squid axons is decreased to about one-half of normal values (by stimulation of the axon in Li-sea water) the Na efflux from the axon becomes insensitive to the presence of K^+ in the sea water bathing the axon. Furthermore, the onset of lack of sensitivity to external K^+ appears to coincide with the appearance of a changed sensitivity of the Na efflux to the presence of Na^+ in the bathing sea water.

Effect of Pituitary Thyrotrophin on the Diglyceride/Triglyceride Interrelationships in Thyroid Tissue

In surviving cellular preparations of thyroid tissue, intermediary metabolism is altered profoundly when 'work' is induced by the addition of pituitary thyrotrophin (TSH)[1]. Heightened phospholipid metabolism is one of the basic features. Thus, TSH augments the incorporation of orthophosphate-^{32}P into certain phospholipids of thyroid slices even in the absence of exogenous organic substrates[2,3]. In the presence of substrate quantities of glucose-^{14}C or albumin-complexed ^{14}C-fatty acids (as potential carbon donors for the glycerophosphate or acyl residues of thyroidal lipids), TSH preferentially channelizes radioactivity into phospholipids rather than neutral lipids[1,4]. Since diglycerides may constitute communal precursors for both phospholipids and triglycerides[5], investigations were instituted to assess whether the disparate activation of phospholipogenesis is accompanied by detectable changes in the diglyceride fraction. The experiments have indicated that the incorporation of carbon atoms into the individual neutral lipid components of thyroid slices during 1–4 h of incubation is altered by TSH. Although TSH does not systematically change the total labelling of neutral lipids from glucose-^{14}C, the triglyceride-^{14}C/diglyceride-^{14}C ratio is reduced, possibly connoting a new 'steady-state' favouring phospholipogenesis.

Individual vessels were filled with 150–200 mg (wet wt.) of canine thyroid slices and incubated at 38° in an

* Suspending media consisted of Krebs–Ringer–bicarbonate containing 2 mg/ml. glucose U-^{14}C (4–5 μc./ml.) ± 0·1 U.S.P. units TSH/ml. in experiments 1–12. The media were further supplemented with 1 μmole/ml. oleate complexed to 10 mg/ml. fat-free albumin in Exps. 8*a* and 9*a*.

† Total neutral lipid (NL) radioactivity is expressed as c.p.m./g of slices (that is, initial wet weight of slices).

‡ TRI and DI refer to the percentages of the total neutral lipid radioactivity that were recovered in the triglyceride and diglyceride fractions respectively. By this convention, 100%—(TRI + DI) represents the fraction of total neutral lipid radioactivity containing monoglyceride, cholesterol, cholesterol esters, free fatty acids, etc.

atmosphere of 95 per cent oxygen + 5 per cent carbon dioxide using diluents and techniques similar to those described earlier[6]. Uniformly labelled glucose-^{14}C (glucose-U-^{14}C; New England Nuclear Corp., Boston, Mass.) 4–5 μc., 2 mg/ml. was added to the suspending medium. Under such conditions, all the phosphoglycerides become labelled *in vitro*, and TSH invariably increases the incorporation of glucose carbons into phospholipids[7]. For the present work, bovine TSH containing 3·52 U.S.P. units/mg was obtained from National Institutes of Health (TSH-B_2 Endocrine Study Section preparations). The hormone was dissolved in Krebs–Ringer–bicarbonate (*p*H 7·4) containing gelatin (2 mg/ml.) to prevent glassware absorption. Sufficient TSH to yield 0·1 U.S.P. unit-ml. incubation medium was added at the beginning of incubation. After defined intervals, the slices were removed and frozen immediately in liquid nitrogen. The tissue was homogenized with chloroform – methanol (2 : 1 v/v) and the crude lipid extract purified using the procedure of Folch *et al.*[8]. Neutral lipids were separated from phospholipids by column chromatography with silicic acid (Bio-Rad). Aliquots were taken for radioactive assay and expressed as c.p.m. of neutral lipid/g initial wet weight of slices. Individual neutral lipid components were separated by thin-layer chromatography (silica-gel *G*) with either diethyl ether–iso-octane (1 : 1 v/v) or petroleum ether–acetic acid–diethyl ether (90 : 1 : 10 v/v/v) as the solvent systems and the inclusion of 0·1 per cent (w/v) butylated hydroxy-toluene to prevent auto-oxidation. The thin-layer plates were sprayed lightly with 0·2 per cent (w/v) 2,7-dichloro-fluorescein in ethanol and the areas of gel corresponding to diglyceride (1,2 and 1,3) and triglycerides were aspirated[9] into counting vials for radioactivity assay by liquid scintillation counting. The counts in diglycerides and triglycerides were expressed as a percentage of the total neutral lipid radioactivity. For statistical analysis, paired *t* tests were performed on the differences of the logarithms of the absolute values observed in the absence (that is, −TSH) and in the presence (+TSH) of TSH. This is equivalent to testing whether the average ratio of values (that is, +TSH/−TSH) is greater than unity[10].

Serial analyses of slices from any one animal indicated that the labelling of neutral lipids from glucose-U-^{14}C progressively increased throughout incubation. In confirmation of our experiences with other species[11], most of this neutral lipid radioactivity was present as glyceride–glycerol at all intervals. The labelling was quite variable in different animals, and the effects of TSH on the incorporation of radioactivity into the total neutral lipids followed no consistent pattern ($P > 0·1$ for Exps. 1–12, Table 1). In other species, we have previously observed comparable variability in the control and TSH-stimulated labelling of thyroidal neutral lipids *in vitro*, and have ascribed it to differences in the prior exposure to TSH and in the availability of endogenous fatty acids for glycerol esterification[1,7]. However, in the work recorded here, regardless of the effects of added TSH on total neutral lipid radioactivity, a striking change in the distribution of radioactivity in the individual neutral lipid components was evident. In the presence of TSH a higher proportion of the neutral lipid radioactivity was recovered in the diglycerides so that the ratio of TRI/DI was reduced significantly ($P < 0·001$ for Exps. 1–12, Table 1).

To assess whether the relative accumulation of labelled diglycerides was due to an impairment of triglyceride synthesis by TSH, added vessels in two experiments were supplemented with 1 μmole/ml. of albumin-complexed oleate to enhance total neutral lipogenesis (Exps. 8*a* and 9*a*, Table 1). The conjoint availability of exogenous glucose and fatty acids caused a three- to five-fold increase in neutral lipid radioactivity in control vessels (as we have previously reported[11]), and an even greater increase in the triglycerides (Table 1). Despite this augmentation in the net labelling of triglycerides, the TRI/DI ratio was still lowered by TSH.

Ongoing investigations with glycerol 1,3-^{14}C afford further corroboration that the TSH-induced relocations in the individual neutral lipids can be dissociated from the availability and biogenesis of fatty acids. In surviving thyroid slices, the incorporation of glycerol radioactivity into fatty acids is negligible although all the glycerides become labelled via esterification of the glycerol-^{14}C. In such circumstances, the ratio of radioactive TRI/DI is consistently lowered by TSH. Work is in progress to characterize the diglycerides on the basis of the position of the acyl residues and to see if more pronounced TRI/DI changes can be unmasked by appropriate subcellular fractionation.

However, even in the absence of such information, the present results indicate that the qualitative pattern of glyceride–glycerol labelling in neutral lipids is altered during the induction of 'work' in thyroid tissue with TSH. Since similar changes were observed during 1–4 h of exposure to the hormone, the phenomenon may reflect a new lipogenic equilibrium which selectively favours cytostructural renewal (that is, phospholipogenesis) and constitutes an integral component of the 'work-hyperplasia' response. Whether it is unique for the thyroid or whether it represents a more generalized phenomenon will depend on the findings in other tissues in which the 'working state' is also attended by an increased turnover of phospholipids[12,13].

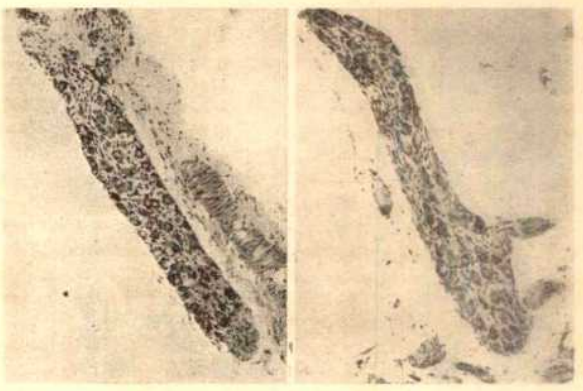
PHARMACOLOGY

Sources of Noradrenaline in the 'Immunosympathectomized' Rat



THE good state of health of cats deprived of the whole length of their paravertebral sympathetic chains and a part of the prevertebral (cœliac and mesenteric) ganglia is well known since the work of Cannon[1]. In contrast, removal of the prevertebral ganglia is not well tolerated in dogs, which do not survive this operation because of intractable diarrhœa[2]. 'Immunosympathectomized' rats, in which extensive irreversible atrophy of the peripheral sympathetic system is produced by injecting, during the first few days of life, an antiserum to the nerve growth factor described by Levi-Montalcini and Booker[3], appear healthy, grow, reproduce and have normal gastro-intestinal function[4].

It was, therefore, of interest to know whether these animals, in addition to having lost most of the neurones of the paravertebral sympathetic chains, had been deprived of their prevertebral abdominal sympathetic ganglia. Hooded rats were injected for the first five days after birth either with antiserum (reconstituted freeze-dried material prepared and assayed by Profs. R. Levi-Montalcini and P. Angeletti), or with 0·9 per cent sodium chloride solution. The rats injected with antiserum had narrow palpebral fissures. One experimental rat and one control were killed at 11 weeks, another pair at 18 weeks of age. The regions of the inferior mesenteric ganglia, of the superior mesenteric and cœliac ganglia, and of the stellate or the superior cervical ganglia were dissected, fixed with bichromate-formaldehyde, sectioned serially and stained with cresyl violet. Whereas stellate and superior cervical ganglia of the rats given antiserum showed the expected atrophy to a thin, mainly fibrous structure containing but few ganglion cells, the prevertebral ganglia were, so far as could be ascertained in structures which show a large degree of individual variation, normal in size and undoubtedly normal in nerve cell density. Fig. 1*b* shows the atrophied superior cervical ganglion of the rat injected with antiserum and killed at 18 weeks, and Fig. 1*a* the corresponding ganglion of its normal control. Figs. 2*a* and *b* are inferior mesenteric ganglia taken from the same pair of rats and, in contrast to the superior cervical ganglia, are indistinguishable in size and fine structure.

a *b*

Fig. 2. Longitudinal sections through inferior mesenteric ganglia. (*a*) Control rat; (*b*) immunosympathectomized rat. (Cresyl violet; × *c.* 66)

The preservation of the prevertebral sympathetic ganglia in the immunosympathectomized rat may well account for the fact that gastrointestinal and reproductive functions are not noticeably impaired. Furthermore, this finding shows that the action of the antibody formed against the nerve growth factor is of even greater specificity than hitherto believed; within the adrenergic neurones it singles out those of the sympathetic chain while sparing those of cœliac and mesenteric ganglia. This might be due to chemical differences between the two types of ganglia, or to the fact that the prevertebral ganglia might be more mature at birth than the paravertebral ganglia.

Finally, a recent observation by Carpi and Oliverio[5] is readily explained by the presence of intact sympathetic ganglia. These authors have found that, under resting conditions, immunosympathectomized rats do not excrete detectable amounts of noradrenaline, but noradrenaline is excreted in normal or supernormal quantities after an injection of amphetamine or after adrenal demedullation. The source of the excreted noradrenaline was tentatively suggested to be extramedullary chromaffin tissue. However, in contrast to the abundance of such tissue in the adult dog, cat and rabbit, very little of it exists in the adult rat[6], and scarcely any was found in the vicinity of the rat's prevertebral ganglia in the present work. Impulses travelling along the neurones of the prevertebral ganglia, on the other hand, are an obvious potential way of releasing noradrenaline in the immunosympathectomized,

adrenalectomized rat. The question which remains open is whether these neurones discharge as a result of neural or in response to some humoral stimuli.

I thank Prof. Eleanor Zaimis for the gift of injected rats, and Mr. B. S. C. Hollands for preparing the sections.

Tumour of the Thymus in Magnesium-deficient Rats

DURING the course of examinations on the effects of magnesium deficiency in rats[1–4], tumours of the thymus developed in a few animals after prolonged periods of deficiency. This incidental finding stimulated a special investigation. Twelve male Holtzman Sprague–Dawley rats (110–125 g body-weight) were fed a magnesium-deficient diet[3] for 95 days; twenty controls received the same diet to which was added 0·6 g of magnesium sulphate per 100 g of diet. Only five deficient rats survived until the end of the experiment. Convulsive seizures accounted for most deaths during the first weeks. Animals dying later showed extensive pleural effusion and ascitis; chronic lung disease with bronchiectatic abscesses was also observed. One rat died with a large thymus weighing 1·6 g after 75 days of magnesium deficiency. Microscopic examination revealed a total replacement of the normal architecture of the gland by sheets of large lymphoid cells. Another abnormal thymus was found at autopsy at the end of the experiment. In this case, thymic tissue had extended in all directions, infiltrating the base of the heart as well as the wall of the œsophagus; the same tissue had also grown retrosternally, reaching the diaphragm. Histologically the appearance was again characterized by a predominance of large lymphocytes or lymphoblasts with numerous mitotic figures (Fig. 1). Limited infiltration with similar cells was also seen in the portal spaces of the liver, in the kidney and in the adrenal cortex. The spleen and lymph nodes were not prominently enlarged and the blood was aleukæmic in both cases. The tumour was transplanted subcutaneously in Sprague–Dawley rats and grew rapidly, killing its host in 20–25 days. No tumour of the thymus was found in rats that were not magnesium-deficient.

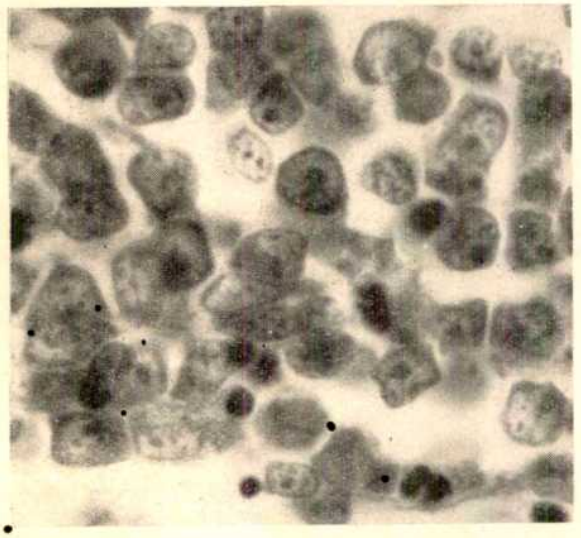

Fig. 1. Typical high-power field of the tumour. Predominance of lymphoblasts in active multiplication (Dominici, × 800)

This tumour is unusual because of its site in this species; spontaneous tumours of the thymus, with or without generalized leukæmia, are uncommon in rats[5–7]. It is also of interest that the tumour was apparently induced by a deficiency in magnesium. The chronic lack of magnesium at the cellular level might increase the removal of magnesium out of the nucleus into the cytoplasm, thus causing chromosomal aberrations and cell mutation, as suggested by Jayson[8]. However, this would not explain the electivity of the thymus. So far, six tumours of the thymus have been observed among 138 magnesium-deficient rats after 75–105 days. The occurrence of lymphoblastic adenoma of the thymus in chronically magnesium-deficient rats was also recorded recently by Jasmin[9].

Previous investigations have shown that magnesium deficiency is conducive to histamine liberation with a reduction of the number of mast cells[1,2,3,10]; it is difficult, so far, to associate these findings with the production of tumours of the thymus.

Rapid Induction by Acetylcholine, Bradykinin and Potassium of a Nociceptive Response in Mice and its Selective Antagonism by Aspirin

HOW aspirin exerts its analgesic action has been much discussed. The findings here reported suggest that it depresses certain chemonociceptive responses at or near their peripheral source, rather than in the central nervous system, and that it acts on these directly, rather than indirectly through suppressing œdema formation.

An apparently nociceptive response of mice to intraperitoneal injection of phenylbenzoquinone or acetic acid has been much used in testing analgesic drugs[1–5]. In this response, which has been described as 'writhing', 'squirming', 'stretching' or 'cramping', the dominant feature is a wave of constriction passing caudally along the abdominal wall, followed by extension of the hind limbs. It will here be called the constriction response. Whittle[6] has proposed that acetic acid and other noxious agents do not elicit this response directly, but by releasing a kinin.

Since substances acting directly are likely to have less latency than those acting indirectly, we have measured the latency of response in mice (T/O strain) after intraperitoneal injection of several endogenous substances known to elicit pain in man. Table 1 compares the speed

Table 1. Speed of Onset of the Abdominal Constriction Response after Intraperitoneal Injection of Various Substances into Mice (T/O Strain)

Substance	Dose mg/kg	No. of mice treated	Cumulative % mice responding by					
			2 sec	5 sec	30 sec	2 min	10 min	30 min

1·8% w/v sodium chloride in distilled water	—	20	0	0	0	0	25	35
Distilled water	—	30	0	0	10	43	43	47

Acetic acid, phenylbenzoquinone and potassium chloride were dissolved in distilled water; other substances in 0·9 per cent sodium chloride in distilled water. The injection volume in all treatments was 10 ml./kg. Weights of salts are given as active acid or base.

* Bradykinin used was synthetic material prepared by the method of Nicolaides and De Wald[15].

† Bradykinin used was synthetic material from ampoules containing chlorbutol, and a sodium acetate–acetic acid buffer, kindly supplied by Sandoz Products, Ltd.

of onset of response to 5 endogenous pain-producing substances with that to acetic acid and phenylbenzoquinone. Acetylcholine bromide, bradykinin and potassium chloride elicited the response in some mice within 5 sec and in most mice within 2 min. No other substance had this rapid time-course of action.

Emele and Shanaman[6] and Whittle[8], using bradykinin from ampoules which contained chlorbutol and sodium acetate–acetic acid buffer, have reported a much slower onset of response to bradykinin than we observed with solid synthetic bradykinin freshly dissolved in 0·9 per cent sodium chloride solution. We therefore tested some ampoules containing 100 μg/ml. of bradykinin and 5 mg/ml. of chlorbutol and acetate buffer. In our hands, the onset of response to this treatment was as rapid as that to bradykinin in saline (Table 1). We also tested chlorbutol, which was effective at 50 mg/kg. Chlorbutol resembled acetic acid in time-course of action, both substances eliciting responses from a few mice within 2 min and from most mice within 30 min of injection (Table 1). After 2 min also, more mice responded to the control injection of 0·9 per cent sodium chloride solution. We conclude that the proportion of mice responding within 2 min of intraperitoneal injection is likely to be a more reliable measure of the activity of bradykinin than that recorded after this period. This conclusion applies also to acetylcholine and potassium.

The question arises of how these agents elicit this response. Its rapid onset after acetylcholine, bradykinin and potassium argues that they cause nociception independently of fluid exudation from blood vessels. The following considerations suggest that these three agents probably stimulate chemonociceptors directly, rather than mechanical nociceptors indirectly, by contracting the gut musculature. (1) Each substance elicits pain from an exposed blister base in man[9]; (2) the spasmolytic drug papaverine (50 mg/kg subcutaneous) did not inhibit the acetylcholine-induced response; (3) 5-hydroxytryptamine induced little or no response, although it causes defæcation in mice[10]; (4) bradykinin in dog, cat and rabbit initially inhibits gut movement[11,12]. Since atropine (0·2 mg/kg subcutaneous) inhibited the response to acetylcholine but at a much larger dose (25 mg/kg subcutaneous) it did not reduce that to bradykinin, these two noxious agents probably excite different chemonociceptors.

Morphine, aspirin and other analgesic drugs inhibit the constriction response to phenylbenzoquinone[1,2,4,5], to acetic acid[3,7] and to bradykinin[6]. These actions were shown in tests in which responses were counted from 10 or more min after injection of noxious agent. Anti-nociceptive tests involving a much shorter duration of noxious stimulation are less likely to be associated with inflammation, as well as being ethically and economically preferable. We have, therefore, measured the potencies of morphine and of aspirin in inhibiting constriction induced by acetylcholine, bradykinin and potassium, over a period of 2 min from the time of injection of noxious agent. At the end of this period, the response to these agents had declined.

Table 2 gives the subcutaneous doses, with fiducial limits, of morphine sulphate, calcium aspirin and sodium salicylate which reduced by 50 per cent the proportion of mice responding to acetylcholine. Since bradykinin and potassium induced constriction in much less than 100 per cent of mice, the lowest doses of drug, which reduced by at least half the proportion of mice responding to these agents, are given in Table 2 without fiducial limits. At all finite doses in Table 2, the effect was significant ($P < 0·01$). When aspirin was given by mouth, it also inhibited acetylcholine-induced constriction, the ED_{50} being 56 (limits 36–88) mg/kg.

Table 2. Potency of Morphine, Aspirin and Salicylate against the Constriction Responses of Mice to Acetylcholine, Bradykinin and Potassium

Constricting agent		Median effective dose (mg/kg)		
Substance	Dose (mg/kg)	Morphine sulphate	Calcium aspirin	Sodium salicylate
Acetylcholine bromide	3·2	0·43 (0·29–0·64)	26 (17–40)	151 (97–235)
Bradykinin	0·4	0·3	200	*N.T.*
Potassium chloride	130	0·3	> 400	*N.T.*

Analgesic drugs were administered subcutaneously 20 min before the constricting agent was injected intraperitoneally. An effective dose was that which reduced by 50 per cent the proportion of mice responding. Fiducial limits ($P = 0·95$) are given where these could be calculated. At all finite doses in the table the effect was significant ($P < 0·01$). *N.T.*, not tested. Weights of salts are those of active acid or base.

Although aspirin did not reduce the proportion of mice responding to potassium to less than half that in the control group, it none the less reduced this proportion significantly. The lowest doses of aspirin, in mg/kg subcutaneously, significantly ($P < 0·05$) inhibiting the response to the noxious agents were: to acetylcholine, 12·5; to bradykinin, 25; to potassium, 50. These values, coupled with the median effective doses in Table 2, show that the order of susceptibility to aspirin was acetylcholine > bradykinin > potassium, whereas morphine was about equiactive against all three agents.

Three considerations support the view that inhibition by aspirin and morphine of the constriction response to acetylcholine, bradykinin and potassium is antinociceptive. (1) The response probably arises from stimulation of nociceptors; (2) aspirin and morphine are known to have analgesic action in man; (3) aspirin does not show other forms of anticholinergic action, such as antagonism of physostigmine toxicity. The differences in potency of aspirin against constriction induced by acetylcholine, bradykinin and potassium suggest that it is acting peripherally on different chemonociceptors, in contrast to morphine which is equally effective against all three noxious agents and is believed to act centrally. These views are consistent with the conclusion of Lim, Guzman, Goto, Braun and Rodgers[13], from cross-circulation experiments, that in dogs aspirin acts peripherally and morphine centrally against nociception induced by bradykinin. In anti-inflammatory tests in mouse peritonitis, aspirin is little more potent than sodium salicylate[7,14]. Its different potency from salicylate against acetylcholine-induced constriction, together with the small latency of the response inhibited, suggest that aspirin may exert its antinociceptive action directly, rather than by reducing fluid exudation from blood vessels. The higher potency of aspirin than sodium salicylate implies that this action does not depend on conversion of aspirin to salicylate.

An alternative, but less likely, explanation of the different effectiveness of aspirin against abdominal constriction in mice induced by acetylcholine, bradykinin and potassium is that aspirin distinguishes in the central nervous system between nociception induced by these three substances.

Inhibition of Uptake of Tritiated-noradrenaline in the Intact Rat Brain by Imipramine and Structurally Related Compounds

Imipramine is one of the most effective drugs for the alleviation of mental depression. There is little information concerning the mechanism of action of this drug at the biochemical level. An impressive body of evidence has been accumulating over the past few years indicating that noradrenaline is involved in behaviour. Although other antidepressant drugs such as monoamine oxidase inhibitors[1], and amphetamine[2], affect cerebral noradrenaline concentration, imipramine was found to have no measurable effect on the level of the neurohumour in the brain[3]. It has been shown that imipramine blocks the uptake of noradrenaline in peripheral tissues[4] and brain slices[5]; however, many other drugs including the tranquillizer chlorpromazine have the same action[5,6]. Because noradrenaline cannot cross the blood-brain barrier, it was virtually impossible to examine directly the action of imipramine or other drugs on the uptake of noradrenaline by the intact brain. We have recently described a procedure which made it possible to introduce tritiated-noradrenaline of high specific activity into the rat brain by an intraventricular injection. The tritiated-noradrenaline is taken up and retained by nerve endings in the brain and then shows the essentially same biochemical behaviour as the endogenous neurohumour[7]. This technique enabled us to investigate the effect of imipramine on the uptake of tritiated-noradrenaline by the intact rat brain. It will be shown that imipramine and structurally related antidepressant drugs but not chlorpromazine block the uptake of tritiated-noradrenaline in the brain.

Sprague–Dawley male rats weighing 300 g received imipramine 1 h before the injection of tritiated-noradrenaline (0·07 μg) into the lateral ventricle of the brain. Two hours after the intraventricular administration of the catecholamine the rats were killed and the brain assayed for tritiated-noradrenaline[8].

Table 1. Inhibition of Tritiated-noradrenaline Uptake in the Rat Brain by Antidepressant Drugs

Treatment	Amount given (mg/kg)	Clinical antidepressant action‖	% of control value
Imipramine	20	Yes	63 ± 3·1*
Desmethylimipramine	20	Yes	64 ± 3·2*
Amitriptyline	10	Yes	77 ± 7·6†
Compound II‡	20	No	99 ± 4·2
Compound III§	20	No	93 ± 3·5
Chlorpromazine	20	No	107 ± 8·6
Chlorpromazine	40	No	91 ± 6·7

* $P < 0.001$. † $P < 0.05$.

Groups of six rats were given the drugs intraperitoneally 1 h before the intraventricular administration of 0·07 μg of *d,l* 7-^{3}H-noradrenaline (5·8 c./m.mole from New England Nuclear Corporation, Boston). Rats were killed 2 h later and the brain assayed for tritiated-noradrenaline. Brain from untreated rats had about 30,000 c.p.m. per g of tissue. Results are expressed in percentage of the control brain tritiated-noradrenaline ± *S.E.M.*

‡ Compound II has the same structure as imipramine except that a dimethylaminoisopropyl side chain is substituted for a dimethylaminopropyl side chain.

§ Compound III has the same structure as chlorpromazine except that a dimethylaminoethyl, ethyl ether side chain is substituted for a dimethylaminopropyl side chain.

‖ Information concerning the antidepressant activity of the various compounds was kindly provided by Dr. Murray Weiner, Geigy Research Laboratories, Yonkers, N.Y.

The uptake of tritiated-noradrenaline by the brain of imipramine-treated animals was markedly reduced (Table 1). The effect of congeners of imipramine and other compounds related in structure, such as amitriptyline and the tranquillizer chlorpromazine, on the uptake of tritiated-noradrenaline was also examined. Desmethylimipramine and amitriptyline reduced the uptake of tritiated-noradrenaline; both these drugs have been found clinically active as antidepressants. A closely related derivative of imipramine with a dimethylaminoisopropyl side chain instead of the dimethylaminopropyl side chain which was found to be clinically inactive as antidepressant had no effect on the uptake of tritiated-noradrenaline in the brain. Chlorpromazine, a tranquillizing drug, which can block the uptake of tritiated-noradrenaline in peripheral tissues and brain slices, had no effect in the intact rat brain.

The uptake of noradrenaline into storage granules of peripheral nerve endings is a major mechanism for the inactivation of noradrenaline[8]. In the periphery it has been shown that drugs which block the uptake of noradrenaline enhanced the physiological actions of the neurohumour[9]. Noradrenaline has been shown to be liberated from nerve endings, react with adrenergic recep-

tors, and then return in part to the stores in the sympathetic nerves[10]. It is likely that a similar mechanism of noradrenaline release and re-uptake is operating in the brain. The experiments described here show that imipramine, desmethylimipramine and amitryptyline block the uptake and binding of noradrenaline by the brain. On the other hand, these structurally related compounds which are devoid of clinical antidepressant activity have no effect on the uptake of tritiated-noradrenaline in the brain. The ability of imipramine to prevent the rebinding of noradrenaline by cerebral tissues may be a mechanism for the antidepressant action of this drug. Such an action of the drug would allow more free physiologically active noradrenaline liberated from the central sympathetic neurones to react with the central adrenergic receptors. The observations that imipramine potentiates the peripheral action of administered noradrenaline[11], that desmethylimipramine will cause hyperactivity after a rapid release of noradrenaline produced by reserpine[12], and that both will potentiate the stimulating action of amphetamine[12,13], a drug that releases noradrenaline in the brain[2], support the mechanism of action of the antidepressant drugs proposed in this communication.

IMMUNOLOGY

Breaking of Immunological Paralysis by Injection of a Specific Depolymerase

THE elaboration by the soil organism *Bacillus palustris* of a depolymerase (*D*3) specific for the long-chained capsular polysaccharide of type III *Diplococcus pneumoniae* (*S*III) (ref. 1) provides an opportunity to explore some of the mechanisms of immunological paralysis induced by *S*III. The polymerase when incubated *in vitro* for prolonged periods with *S*III cleaves it to hexasaccharides and smaller units[2]. It could readily be shown that when the products of this reaction are injected into adult mice they do not elicit an immune response. Thus, 5/5 mice injected with 0·5 ml. of a 21-h reaction mixture containing 40 μg *S*III and 50 viscosity units of *D*3 failed to form antibodies. When these mice were later injected with 0·1 μg *S*III they all formed antibodies against the *S*III. When *D*3 is injected intravenously into mice which 12 h previously had received 100 μg *S*III it rapidly clears the antigen from the circulation so that within 12 h *S*III is no longer detectable by either the micro-precipitin or the complement fixation tests. The former test detects 0·1 μg and the latter 0·01 μg antigen. Although no *a priori* evidence existed it seemed just possible that the enzyme might even enter the cells containing the *S*III and relieve the immunological paralysis caused by the injection of relatively large amounts of *S*III.

* Titrations were commenced with a serum dilution of 1 in 4. The figures are the reciprocals of the serum dilution at which an end-point was noted.
† Live/total. Not all mice were challenged.

Four separate experiments were done over 2 years, but for convenience the results are presented collectively. Two measures of immunity were used. Mice were bled from the retro-orbital sinus and their sera, after absorption with sheep cells, titrated for antibodies to *S*III using as antigen a filtrate of type III *D. pneumoniae* coated to sheep erythrocytes[3]. In some experiments some mice were challenged about one month after *D*3-treatment with 100–200 lethal doses of type III *D. pneumoniae*.

The intraperitoneal injection of 0·1 μg *S*III into 12–14-week-old male *CAF* mice results, whether or not it is followed 2 days later by the intravenous injection of *D*3, in the formation of relatively high titres of antibodies to *S*III (Table 1). On the other hand, when mice were injected with 100 μg or 2·0 mg *S*III and bled at intervals over the next 24 weeks *S*III antibodies were never detected. Entirely different results were noted when *D*3 was injected into the paralysed mice. If the enzyme was injected 6 h to 4 days after the paralysing dose of *S*III, then the mice were no longer paralysed and indeed 40/45 animals formed detectable—albeit relatively low-titred—antibodies against *S*III. As the interval between the injection of antigen and enzyme was increased fewer mice were relieved of their paralysis and they formed only low titres of antibodies against *S*III. Thus, only 7/39 paralysed mice injected with *D*3 5–18 days after *S*III and 0/23 injected 2–3 months after *S*III formed detectable antibodies. The results of the challenge test essentially confirm these findings and the slightly less impressive results obtained with this method (the figures are 19/32 for the period 6 h–4 days; 7/26 for the period 5–18 days and 0/5 for the 2–3-month period) might be attributed to the waning of immunity in the interval between the injection of *D*3 and the subsequent challenge. As an additional control some of the paralysed mice were injected intravenously with saline at the same time as other mice were injected with *D*3. They were still paralysed when bled one week later.

Similar results were obtained with those mice injected with 2·0 mg *S*III. Seventeen of 18 mice injected with *D*3 during the 4 days after the *S*III injection were freed from their paralysis: 13/19 injected with *D*3 between 5 and 10 days after *S*III were also freed of paralysis whereas 0/14 injected with *D*3 69 days after *S*III were able to produce detectable antibodies to *S*III.

It must be stressed that the injection of enzyme into paralysed mice not only removes the paralysis but also results in the formation of antibodies against *S*III. Thus, in no instance did a mouse which had failed to form antibodies after the injection of *D*3 then form antibodies if injected with 0·1 μg *S*III, even if this injection was delayed for several weeks.

That immunological paralysis can be broken by *D*3 and that there is a critical period during which the enzyme is operative suggests the possibility that the *S*III or part of it is integrated into a specific cell-type before paralysis can occur. The cell type may not evolve until some time after the injection of antigen or integration may not occur until after several cell divisions.

An observation which failed to agree with the results recorded here is that in some rare instances mice injected 9 months previously with paralysing doses of *S*III, either spontaneously or after the injection of 0·1 μg *S*III, formed low titres of *S*III antibodies. It will be of interest to determine the effect of *D*3 at this time. It will also be of interest to determine by means of fluorescent staining if the cells of mice injected with *D*3 after *S*III still contain specific staining material.

Towards the end of this work a note appeared by Salzman and MacLeod[4] reporting failure to break immunological paralysis when *D*3 was injected into mice which had received 25 μg *S*III. The abstract contained no further details, and the many possible variabilities probably explain the difference between their results and those reported here.

I thank Dr. J. Campbell for supplies of *S*III and *D*3. This work was supported by a grant from the U.S. National Institutes of Health (*CA*–05175).

Antibody Production by Leucocytes in Peripheral Blood

The immune response to foreign antigens is focused in lymphoid tissue, notably spleen and lymph nodes; cells from these sites manifest the entire spectrum of immunological capabilities. Despite the fact that a considerable proportion of leucocytes in peripheral blood are of lymphoid origin and have been used to transfer hypersensitivity states, their role in the production of humoral antibody has been uncertain. It was recently shown by Hullinger and Sorkin[1] that circulating leucocytes (buffy coat) from rabbits hyperimmunized with human serum could produce significant amounts of specific antibody. By a quite different means we have obtained direct evidence for the elaboration of specific antibody *in vitro* by such cells, thus confirming and extending their findings.

NIH rabbits, 4–5 months of age, were injected once with 5 μg of *Salmonella enteritidis* somatic polysaccharide[2] given intravenously. At appropriate intervals the animals were bled by cardiac puncture and the blood collected in heparin. To facilitate separation of leucocytes, 20 ml. of heparinized blood was added to two volumes of 3 per cent dextran (mol. wt. 188,000), mixed for 10 min and then allowed to stand for 20 min, after which the leucocyte-rich plasma was drawn off and centrifuged for 10 sec at 250*g* to further remove erythrocytes. The supernatant was then centrifuged at 150*g* and the sedimented leucocytes were resuspended in Eagle's medium. The total number of leucocytes usually obtained was approximately 5×10^7; contaminating erythrocytes averaged about 10 per leucocyte. For enumeration of antibody-forming cells the localized hæmolysis technique of Jerne[3] was used with sheep erythrocytes which had been coated with *S. enteritidis* endotoxin previously treated so as to facilitate its uptake by red cells[4]. When this polysaccharide is used to modify the antigenicity of erythrocytes, lymphoid cells of normal rabbits yield few or no zones of hæmolysis (plaques) (< 1 per 10^6 lymphoid cells). When the erythrocyte itself serves as both antigen and indicator, there is a major element of uncertainty in assessing data such as that obtained for the early inductive phase of antibody formation, inasmuch as cells secreting natural hæmolysin are almost invariably present in significant numbers. As antigens, the somatic polysaccharides offer a number of important advantages, one being that in normal rabbits the number of plaque-forming cells discerned with the *S. enteritidis* coated red cells, for example, are essentially the same as those obtained with uncoated erythrocytes. Thus, even a modest increase in numbers of plaque-forming cells specific for this somatic polysaccharide can be detected.

Five days after rabbits are injected with 5 μg of the *S. enteritidis* polysaccharide an average of 2,000 plaques per 10^6 spleen cells are seen when these cells are plated on coated erythrocytes[5]. In contrast, plating these spleen cells on normal sheep erythrocytes disclosed no significant increase in plaque formation (< 1 per 10^6 cells). Moreover, similar low 'background' activity was seen when these spleen cells were plated on erythrocytes coated with immunologically unrelated somatic polysaccharides. These findings attest to the specificity of the antibody detected in this system.

In an investigation of the characteristics of the immune response to these somatic polysaccharides, it was soon evident that while most of the antibody-forming cells were present in spleen[5], appreciable numbers of plaque-forming cells were also discerned in leucocyte suspensions from peripheral blood when these were mixed with polysaccharide-coated sheep erythrocytes, plated, incubated and then exposed to guinea-pig complement. The findings on 44 rabbits are summarized in Table 1. It is evident that within 3 days after the single antigenic stimulus large numbers of antibody-producing cells are found in the circulation. It was possible to process the leucocyte suspensions so as to remove the granulocytes, leaving a population consisting predominantly of small lymphocytes, which nevertheless retained the same level of plaque-forming activity. There was, however, no apparent correlation between the percentage of lymphocytes in the leucocyte suspensions and the numbers of plaques obtained. The maximum number of plaque-forming cells appeared in blood at about day 4; in spleen, on the the other hand, the peak was attained consistently on day 5. It is also noteworthy that whereas in spleen there is a progressive decline in the number of plaque-forming cells between days 5–30, followed by the persistence of

Table 1. Production of Anti-polysaccharide Plaques by Peripheral Leucocytes of Rabbits injected with *S. enteritidis* Somatic Antigen

* Peripheral cells from each rabbit were also plated on uncoated (normal) sheep erythrocytes. Generally these values were in the range of 1 plaque-forming cell per 10^6 leucocytes, or less. In the few instances where higher control values were obtained these were used to adjust the results obtained with polysaccharide-coated erythrocytes.
† PFC, plaque-forming cells.

significant numbers of these cells for many weeks, in peripheral blood plaque-forming cells are suddenly no longer evident after about 1 week. Again, in contrast to the findings with spleen cells, the response of the peripheral cells was rather erratic, varying considerably from animal to animal. Since the animals were killed for parallel investigations on other lymphoid organs, it was not feasible to obtain serial blood samples from individual rabbits. This could, in part, account for the variable results.

Despite the less consistent appearance of antibody-producing cells in blood, as compared with the uniformity of response in spleen, the fact remains that during the productive phase of antibody synthesis the general pattern of response by peripheral cells is not unlike that of spleen. Consequently the appearance of plaque-forming cells in blood is not likely to be a fortuitous occurrence, but rather a meaningful facet of the host's response to this antigen.

It remains to be determined whether the plaque-forming cells found in peripheral blood are derived from other lymphoid sites, such as spleen, thymus, or lymph nodes, or whether blood leucocytes *per se* are directly stimulated by this antigen. Since it is believed that lymphocytes continually migrate through lymph nodes and other lymphoid structures into lymph and through the blood[6], it is entirely possible that these cells originate in sites traditionally associated with antibody production. The aforementioned variability in numbers of plaque-forming cells in peripheral leucocytes may also be an indication that these circulating cells have emerged from other lymphoid sites.

Although our findings affirm the report by Hullinger and Sorkin on antibody production by peripheral blood leucocytes, there are also noteworthy differences. Since these workers hyperimmunized rabbits with a soluble protein the ensuing immune response probably consisted of 7*S* γ-globulin antibody production. In contrast, the present work was based on an antigenic stimulus consisting of a single injection of 5 μg of polysaccharide which has been shown[7] to lead to the production of macroglobulin antibody exclusively. The considerable difference in proportion of reactive cells in our respective investigations is understandable in view of the major differences in the type of antigen used, the immunization schedule utilized and the ensuing immunoglobulin produced.

While by no means comparable to the population of antibody-forming cells in other lymphoid organs (spleen with intravenous injection and draining lymph nodes with subcutaneous administration) the magnitude of the contribution by peripheral cells to the response is none the less appreciable. The contribution of these peripheral cells to the overall immune response can be approximated by considering the blood volume to be 13 per cent of the body-weight, and the concentration of lymphocytes in blood as averaging 35 per cent of the total leucocytes. On this basis, the total population of blood lymphocytes in the rabbit is estimated to be 600 million; of these an average maximum of 110,000 are antibody-producing cells. It is useful to compare these figures with those for the major organ of antibody production in this system, namely spleen; here the number of cells also average about 600 million; of this total about 1·2 million are antibody-producing cells at the peak of response. Accordingly, it is estimated that of the cells in the rabbit which are committed to the production of antibody specific for this polysaccharide, as much as 10 per cent may be present in peripheral blood.

A Continuous-flow Micro Double Diffusion Technique with Cellulose Acetate

The value of the Ouchterlony double diffusion test in the analysis of antigen-antibody reactions is well established. In the micro modification, introduced by Wadsworth[1] and developed by Crowle[2], a continuous-flow diffusion system was achieved by using wells made in 'Perspex' templates. Relatively large volumes of reactants diffuse under hydrostatic pressure into a thin layer of agar, greatly increasing the sensitivity and resolution of the test while economizing on reagents[3]. However, the use of agar in the micro-technique has certain disadvantages. Primarily, there is the considerable risk of complete loss of the reaction due either to tearing of the fragile agar layer when the template is removed, or to its loosening and washing off during the staining procedures. Splitting and

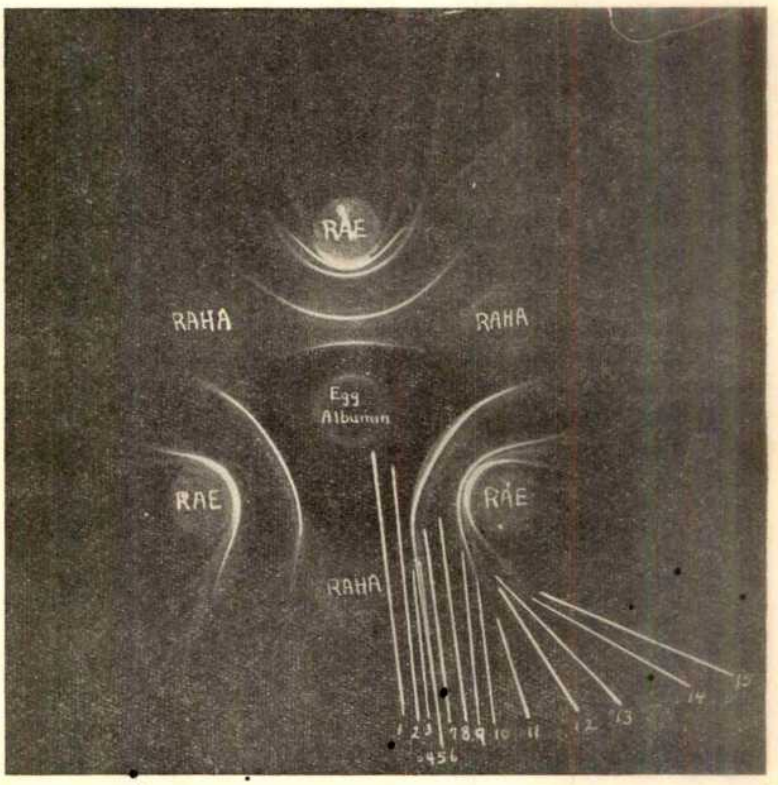

Fig. 1. Micro double diffusion reaction in cellulose acetate between egg albumen, rabbit anti-egg albumen serum (*RAE*), and rabbit anti-horse albumen serum (*RAHA*) stained with Ponceau *S*

distortion of the agar layer during drying may also occur. Secondly, the test is relatively inflexible in that the *p*H and electrolyte concentration of the agar cannot easily be varied, and, finally, variations are encountered with different batches of agar both as regards their mechanical stability and the reactions developing in them[3].

For these reasons, we have developed a technique designed to combine the advantages of the continuous-flow system with those offered by the use of cellulose acetate as a medium for immunodiffusion[4].

Cellulose acetate strips ('S and S Cellulose Acetate Strips for Electrophoresis', Consolidated Laboratories, Canada, Ltd.) are cut transversely into pieces approximately 2·3 cm × 5 cm. The strips are soaked by floating them on the buffer to be used and are then immersed until required. 'Perspex' templates of the type described by Crowle[2,3] are used, and care must be taken to keep the under surface of each template perfectly smooth and polished. To mount each template a wet cellulose acetate strip is laid lengthwise on a clean glass slide and the template is placed at one end of the strip. Then the template is slipped into a central position along the wet surface, eliminating air bubbles in the process. Excess buffer is blotted from the ends of the cellulose acetate strip which should extend beyond both ends of the template. Blotting is continued until the paper visible at the bottom of the wells just changes from a shiny to a matt appearance. The prepared slides are placed, in pairs, into small moisture chambers (square Petri dishes, containing damp filter paper).

The test materials are applied with finely drawn-out glass pipettes, and all the wells of the individual templates should be charged as quickly as possible. If the preparation is satisfactory there will be no leakage between the template, paper and slide interfaces, and there will be no change in the appearance of the cellulose acetate at the bottom of the unfilled wells as the neighbouring wells are filled.

The individual moisture chambers are placed together into a larger container which is sealed more efficiently and preserves a moist atmosphere throughout incubation. The precipitin reaction develops at approximately the same rate as in agar. With the reagents tested, 40–48 h at room temperature was most satisfactory.

After incubation, the templates are removed by holding the slides under running tap water. The strips are washed in physiological saline for a minimum of 4 h and then for 10 min in distilled water. Precipitin lines are stained with 0·2 per cent Ponceau *S* (Consolidated Laboratory) in 3 per cent trichloroacetic acid or 0·1 per cent thiazine red *R* ('*CI* 14780') in 1 per cent acetic acid for a minimum of 10 min. Background differentiation is effected with 3–5 per cent acetic acid baths. After a distilled water wash, the strips are drained and dried at room temperature.

When the cellulose acetate strips are completely dry, they are immersed in 'Whitemor Oil No. 120' (Consolidated Laboratory), which immediately makes them transparent. The oil-soaked strip is layered on a slide and a coverslip placed over the reaction area. After the excess oil is blotted with filter paper and the cellulose acetate is trimmed to coverslip size, clear varnish (nail enamel) is used to seal the edges, making a permanent mount. To allow photographic evaluation as recommended by Crowle[3], and because very faint lines sometimes become visible after clearing where none had previously been evident, clearing and mounting the precipitin reaction are especially important parts of this micro-immunodiffusion technique and should be routinely performed.

Fig. 1 is an enlargement of a micro double diffusion reaction in cellulose acetate between 0·7 per cent egg albumen in physiological saline (Nutritional Biochemicals, crystalline egg albumen, lot 6081), rabbit anti-egg albumen serum (*RAE*) and rabbit anti-horse albumen serum (*RAHA*) (commercial preparation). A total of 15 separate component lines can be counted in the precipitin reaction between the egg albumen and its specific antiserum (*RAE*). It has been found, by direct comparison of this reaction in agar and cellulose acetate, that a more complex system of component lines with better separation and resolution was revealed using cellulose acetate.

In a titration of horse antitoxin (diphtheria antitoxin, globulin modified 40,000 I.U., Connaught Medical Research Laboratories) with diphtheria toxoid ('Diphtheria Toxoid', Connaught Medical Research Laboratories, lot No. 1975–1) 0·26 units and 0·13 units antitoxin were readily demonstrated using a 1 Lf/ml. dilution of toxoid. These dilutions failed to give a positive ring test.

A variety of cellulose polyacetate membranes are available for filtration and electrophoresis and a comparative examination of different membranes is planned having special interest in the effect of different porosities in achieving separation of components. Further investigations will involve the application of scanning and elution techniques in the development of qualitative and quantitative analyses.

HÆMATOLOGY

Blood Group Antigen Xg^a in Gibbons

The antigen Xg^a, which in man is an X-linked dominant character[1], was looked for in various mammals but was found only in gibbons. It was not found in the following animals: 67 chimpanzees (*Pan satyrus*), 2 gorillas (*Gorilla gorilla gorilla*), 20 orangutans (*Pongo pygmaeus*), 60 baboons (*Papio cynocephalus*), 31 Celebes black apes (*Cynopithecus niger*), 4 drills (*Mandrillus leucophaeus*), 10 rhesus monkeys (*Macaca mulatta*), 5 pigtailed monkeys (*Macaca nemestrina*), 1 marmoset, 20 mice and 37 dogs.

In testing the cells of some of these animals heteroagglutinins in the anti-Xg^a plasma had to be circumvented: heteroagglutinins in the antiglobulin serum caused difficulty in testing the orangutans, which therefore had to be grouped by absorption tests. All the primates listed above have been tested for other blood groups[2–5].

Thirteen gibbons were tested, with the following results:

	Antigen Xg^a	
	present	absent
Males	3	4
Females	4	2

These gibbons were not known to be related to each other; they are maintained at the Delta Regional Primate Research Center. Details of their other blood groups are available[2–6]. The thirteen may be identified as follows: males Xg(a+) Britt, 404 and 406; males Xg(a−) Charlie, Viet, 76 and 78; females Xg(a+) Kerry, Thai, Suma and Burma; females Xg(a−) Indo and 403. Indo is the one *Hylobates pileatus* member, the other twelve belong to *Hylobates lar lar*.

Two examples of human anti-Xg^a were used for the tests on the gibbons[1,7]. In man this antibody reacts only by the antiglobulin method and it was so used on the animal red cells. With the gibbon cells and by the antiglobulin method heteroagglutinins caused but little

trouble: however, the results were confirmed by absorption tests.

How alike the gibbon Xg^a antigen is to that of human beings may ultimately be seen from chemical analysis, but at present it is indistinguishable: absorption of the two available examples of anti-Xg^a by Xg(a+) gibbon cells removed the antibody for human and for gibbon Xg(a+) cells, as did absorption by human Xg(a+) cells. Absorption by gibbon or human Xg(a−) cells did not remove the antibody for Xg(a+) members of either species.

The distribution of the antigen in the two sexes suggests that it may be X-linked in the gibbon as it is in man. If the antigen were an autosomal character in the gibbon the chance of observing such a distribution would be 1 in 3. It is hoped that more gibbons will be available in 1965 and that the question of X-linkage will then be settled.

That the gibbon Xg^a antigen may be X-linked is perhaps the less surprising since hæmophilia is X-linked in the dog[8] as it is in man, and the clotting factor deficiency appears to be the same[9]. The presence of Xg^a in the gibbon can scarcely be considered taxonomically important, though X-linkage, if confirmed, would suggest that there is some powerful evolutionary reason why the gene for this antigen should be located on the X chromosome.

We acknowledge the following help. Dr. J. Moor-Jankowski, chief, Division of Experimental Immunogenetics and Oncology, Yerkes Primate Research Center, Emory University, Atlanta, Georgia, stimulated us to test primates and sent us the samples: ten of the chimpanzees and all the gibbons were obtained by Dr. Moor-Jankowski through the kind collaboration of Dr. A. J. Riopelle, director, Delta Regional Primate Research Center, Tulane University, New Orleans, Louisiana. Advice on the taxonomy of the primates was given by Dr. W. C. Osman Hill, associate director, Yerkes Regional Primate Research Center. Dr. L. H. Collier, Medical Research Council, Trachoma Research Unit, Lister Institute, London, provided some of the samples from baboons, Dr. N. A. Mitchison, National Institute for Medical Research, Mill Hill, the samples from mice, and Dr. H. C. Rowsell, Ontario Veterinary College, Guelph, Ontario, the samples from dogs.

Dr. J. D. Mann, Butterworth Hospital, Grand Rapids, first began the search for the antigen Xg^a in animals, Dr. Victor McKusick, Moore Clinic, Johns Hopkins Hospital, Baltimore, suggested the testing of dogs, and Dr. Kurt Benirschke, Dartmouth Medical School, Hanover, New Hampshire, the testing of apes.

We thank Dr. A. Cahan, Knickerbocker Biologics, New York, and Dr. I. A. Cook, North Scotland Blood Transfusion Service, Inverness, for supplies of the anti-Xg^a plasma.

PATHOLOGY

Serum Enzymes in the Jaundiced Homozygous Gunn Rat

In the course of investigations using jaundiced Gunn[1] rats, serum enzyme examinations were performed on these rats and on those of a Wistar strain. Jaundiced homozygous Gunn rats are lacking in hepatic glucuronyl transferase using bilirubin as a substrate. Many workers have established that hepatic cellular damage is associated with elevation of certain serum enzymes, and an investigation was undertaken to compare the serum enzyme levels in jaundiced Gunn rats and those of a Wistar strain to determine whether the jaundice was associated with raised serum enzyme activities.

Blood specimens were obtained from the tail vein of male rats and the serum was analysed for glutamic-oxalacetic and glutamic-pyruvic transaminase[2], lactic dehydrogenase[3], cholinesterase[4] and aldolase[5]. Normal values for the activities of the five serum enzymes were established by analysing random blood samples in 25 Wistar strain rats. The serum enzyme activities in jaundiced Gunn rats were established by analysing random blood samples in 16 rats.

Table 1. Serum Enzyme Activities in 16 Jaundiced Gunn Rats and 25 Rats of a Wistar Strain

Results (units/ml.) given as mean and standard deviations

	Gunn rats	Wistar rats
Glutamic oxalacetic transaminase	117 ± 24	124 ± 53
Glutamic pyruvic transaminase	36 ± 9	41 ± 13
Lactic dehydrogenase	2,540 ± 560	2,408 ± 662
Aldolase	133 ± 34	128 ± 36
Cholinesterase	51 ± 17	55 ± 24

There was no significant difference between the enzyme levels in jaundiced Gunn rats and those of the Wistar strain (Table 1). The transaminase levels in these rats were lower than those found in male Sprague–Dawley rats by Altland and Highman[6]. They found levels of 261 ± 25 units and 63 ± 3 units for glutamic-oxalacetic and glutamic-pyruvic transaminase, respectively. Lactic dehydrogenase and aldolase activity was greater than that found by Altland and Highman, who found levels of 1,082 ± 72 units and 68 ± 3 units for lactic dehydrogenase and aldolase, respectively. Sibley and Lehninger[5] found a range of aldolase activity of 30–100 units/ml. in male Sprague–Dawley rats.

The results show that lack of glucuronyl transferase in jaundiced Gunn rats is not associated with increased serum enzyme activity for those enzymes tested.

We thank Dr. Barbara Billing for a gift of Gunn rats and the British Empire Cancer Campaign for Research for financial assistance.

Demonstration of Hydroxyindole-O-methyl Transferase, Melatonin, and Serotonin in a Metastatic Parenchymatous Pinealoma

Pinealomas have been associated with two endocrine syndromes: destructive, non-parenchymal lesions frequently produce precocious puberty in young boys; true parenchymatous tumours have been found in children with delayed pubescence[1]. Little is known about the biochemistry of these tumours, or about possible mechanisms by which they exert their pathological effects on gonad function.

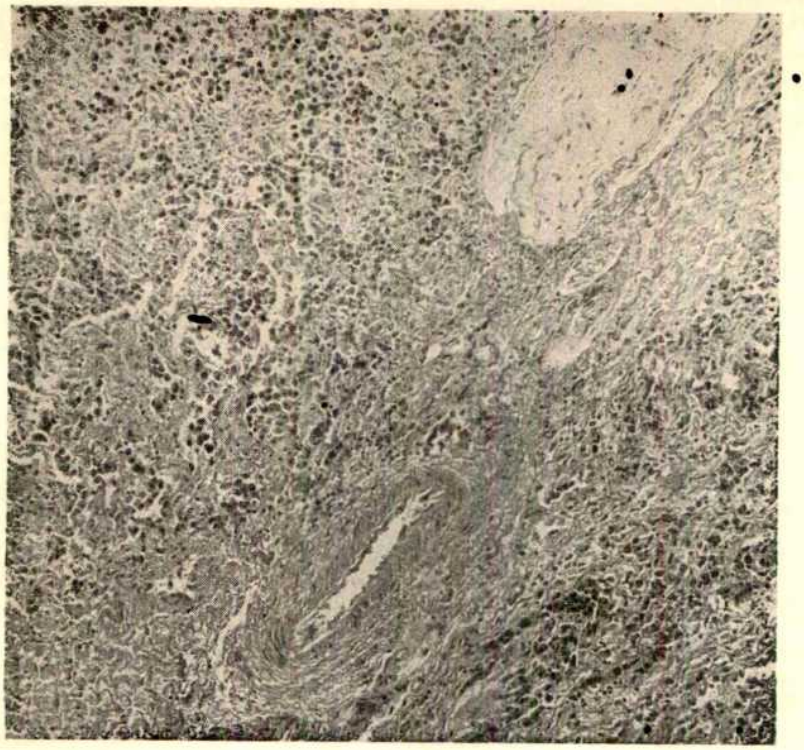

Fig. 1. Section of subcutaneous metastasis of parenchymatous pinealoma (haematoxylin and eosin; × c 52)

Recently, considerable information has become available concerning the formation and actions of certain indoles in the pineal gland[2]. Of particular interest has been the finding of high concentrations of melatonin (5-methoxy *N*-acetyltryptamine) in this gland[3], and the observation that only the pineal has been shown to contain the enzyme (hydroxyindole-*O*-methyl transferase) required for its synthesis[4]. Melatonin[5] and another pineal methoxyindole, methoxytryptophol[6], have both been shown to exert an inhibitory effect on gonad growth and the œstrous cycle in rats.

We have had an opportunity to examine a specimen of metastatic parenchymatous pinealoma from a 14-year-old boy with symptoms of delayed pubescence. The patient was first seen at the age of 9·5 years because of symptoms of increased intracranial pressure. A pneumoencephalogram revealed evidence of a mass in the pineal region; this was treated with irradiation with lasting remission of the intracranial symptoms. Two years later, the patient was seen for symptoms arising from an osteolytic lesion in the left femur, which was consistent histologically with metastatic pinealoma. This lesion also responded well to irradiation. Recently, the patient has developed subcutaneous nodules; one of these was biopsied and examined histologically (Fig. 1), and a 4-g specimen was utilized for the investigations which are described. A detailed report of the clinical findings in this patient will be given elsewhere. At the present time, he shows no evidence of penile or testicular growth, or axillary or pubic hair.

Giarman *et al.* have found that the human pineal gland contains relatively large amounts of serotonin[7] (0·36–22·82 μg/g). The serotonin content of this tumour was examined by the fluorometric method of Bogdanski *et al.*[8] and by the ninhydrin method of Vanable[9]. The content of this amine was found to be 8 μg/g by the former method and 3 μg/g by the latter. These differences are probably related to the unequal distribution of the various tissue components in the tumour samples (Fig. 1).

The presence of pineal methoxyindoles in the tumour was examined by thin-layer chromatography of a chloroform extract of the tissue. The solvent system used was chloroform–methanol, 94 : 6. Using 30 mg of tissue, a compound having the same R_F and colour reactions as authentic melatonin was clearly demonstrable. Since 10 mμg of authentic melatonin would probably be visible as a single spot in these circumstances, the tumour tissue was estimated to contain 0·3 μg/g of melatonin, or about as much as is found in bovine pineals.

Another sample of tumour tissue was assayed for hydroxyindole-*O*-methyl transferase activity by a method described before[10]. The tumour was capable of synthesizing at least 10 μg of melatonin (from *N*-acetylserotonin and ^{14}C-*S*-adenosylmethionine)/g tissue/h. The formation of ^{14}C-melatonin was confirmed by cochromatography with the authentic compound in solvent systems described before[11].

These observations provide the first demonstration of hydroxyindole-*O*-methyl transferase in tissue other than normal pineal. The presence of this enzyme, along with a high concentration of serotonin (in a non-carcinoid tumour), may be useful tools in the diagnosis of this rare lesion. Melatonin has been shown to depress gonad growth and some aspects of gonad function in the rat[5]. The activity of the melatonin-synthesizing enzyme varies with a diurnal cycle, which is controlled by environmental lighting. It is possible that the sustained synthesis of melatonin or related substances by this tumour has contributed to the delayed pubescence seen in this patient.

We thank Drs. John Daly, Kenneth Melmon, and Solomon Snyder for help with some of the indole assays.

RADIOBIOLOGY

Adenosine-triphosphatase and Potassium Retention in X-irradiated Erythrocytes

The total adenosine-triphosphatase (ATP-ase) activity of erythrocytes can be divided into two portions, one of which is inactive in the absence of sodium and potassium ions, or in the presence of ouabain; the potassium-

dependent fraction is associated with active ion transport in the cell[1,2]. Recent reports have suggested that X-irradiation (0·9–4·5 kr.) of erythrocytes inhibits both the active ion transport and the specific ATP-ase associated with this process[3,4]. We have re-investigated this problem to determine whether ATP-ase inhibition could account for the loss of potassium ion from X-irradiated erythrocytes.

The potassium-dependent ATP-ase was inhibited only by 1 mM ouabain in rat erythrocyte ghosts (Fig. 1) or hæmolysates. The high concentration of ouabain required to inhibit this ATP-ase corresponds well with the high concentrations required to inhibit active ion transport in rat thyroid or uterus[5,6]. Surprisingly, rat brain appeared to contain another ATP-ase with 200-fold greater sensitivity to ouabain (Fig. 1); it is noteworthy that the metabolism of rat brain is also affected by very low concentrations of ouabain[7]. In both cases, the inhibitory effect of ouabain was rapidly reversible on dilution.

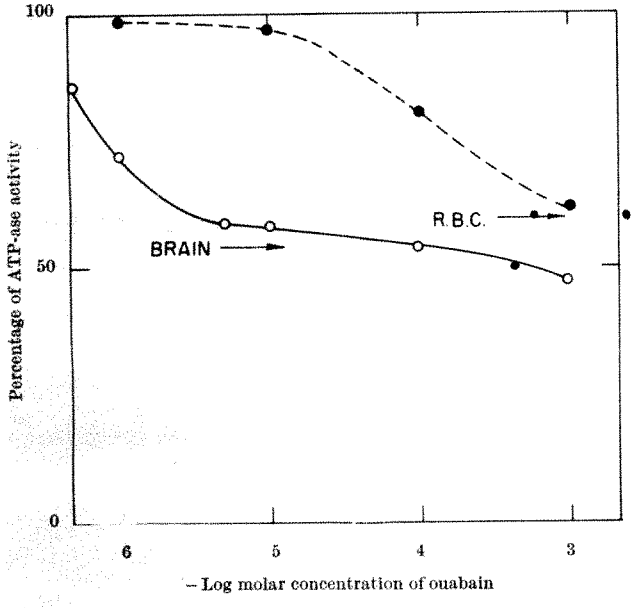

Fig. 1. Inhibition of the ATP-ase activity of rat brain homogenate and of rat erythrocyte ghosts by ouabain. The horizontal arrow in each case indicates ATP-ase activity in the absence of potassium ion. Erythrocytes from 7-week female rats were washed several times with 0·15 M NaCl and were then lysed in 5 mM *tris*-hydroxymethylaminomethane (*tris*) buffer plus 1 mM ethylenediaminetetraacetate (EDTA) at *p*H 8; the erythrocyte ghosts were recovered by centrifugation at 25,000*g* and 0° C for 30 min and washed free of hæmoglobin in the same *tris*-EDTA solution. Rat brains were homogenized with 100 volumes *tris*-EDTA solution, 0·1 ml. homogenate being diluted to 3 ml. in the enzyme assay mixture. ATP-ase activity was estimated from the rate of liberation of inorganic phosphate by the enzyme preparation at *p*H 7·4 and 37° C in the presence of 100 mM NaCl, 20 mM KCl, 6 mM $MgSO_4$, 1 mM EDTA, 10 mM *tris* buffer and 3 mM adenosine triphosphate

The concentrations of ouabain required to inhibit the potassium-dependent ATP-ase in rat liver, kidney and thymus were found to be similar to those shown for rat erythrocytes. The importance of this ouabain-sensitive enzyme for the maintenance of intracellular potassium-levels could readily be demonstrated with liver slices. When incubated for 1 h at *p*H 7·4 and 37° C in a Ringer–glucose–phosphate medium, control liver slices retained their potassium, while the potassium-level in slices with 1 mM ouabain dropped to 52 per cent of the control value. This effect of ouabain was reversible; when the liver slices were rinsed free of ouabain and incubated at 37° C in fresh Ringer medium for another hour, their potassium content increased again to 85 per cent of the control value. Incubation of control liver slices for 1 h at 0° C instead of 37° C resulted in a loss of 61 per cent of their potassium; the subsequent addition of 1 mM ouabain completely prevented the normal re-accumulation

Table 1. Effect of Ouabain and X-irradiation on Potassium-levels in Rat Erythrocytes

Intact, washed erythrocytes were suspended in 15–20 volumes of a modified Krebs–Ringer solution containing 5 mM glucose, 10 mM phosphate buffer at *p*H 7·4, two antibiotics (penicillin and streptomycin) and 20 per cent calf serum; the serum was not essential but did reduce erythrocyte fragility and hæmolysis. After incubation, the cells were centrifuged down and washed once with 0·15 M NaCl. Potassium concentrations in the cells were measured on a flame photometer with an internal lithium standard. X-ray exposures (1–12 kr./min) were measured with a ferrous sulphate dosimeter[13].

of this potassium when the potassium-depleted slices were incubated at 37° C during the second hour. Similar results have been reported recently by Judah and Ahmed[8].

Active ion transport did not seem to be essential for potassium retention in rat erythrocytes. Neither low temperature nor low temperature plus 1 mM ouabain produced any appreciable loss of intracellular potassium within 20 h (Table 1). Ouabain did produce some loss of potassium from control erythrocytes at 37° C, but this loss was very slow. Active ion transport across the cell membrane might be responsible for the high concentrations of potassium and low concentrations of sodium inside the normal erythrocyte, and might also compensate for any slow leakage of potassium from the cell. However, these results suggest that potassium ion, once transported to the interior of the erythrocyte, must be held there in the cellular structures, and that a cessation of active transport does not necessarily result in a rapid equilibration of ion concentrations across the external cell membrane. The same conclusion appears to hold for intact thymus lymphocytes[9], but not for liver cells. The latter, in contrast to erythrocytes, not only lose and regain potassium rapidly *in vitro* but also equilibrate rapidly with extracellular potassium *in vivo*[10].

No evidence could be obtained for the immediate inhibition of active ion transport or of the associated ATP-ase by moderate doses of X-irradiation. Exposure of the liver slices to 60-kr. X-rays at 0° C did not affect the normal re-accumulation of potassium during subsequent incubation at 37° C. Direct measurements of the ouabain-sensitive ATP-ase activity of erythrocytes also showed very little change following X-ray doses from 1 kr. up to 60 kr., either with intact rat cells, with rat erythrocyte hæmolysates or with ghost preparations from rat and human erythrocytes. (The total ATP-ase activity also remained constant in these experiments.) Despite the absence of any appreciable effect on ouabain-sensitive ATP-ase, X-irradiation does increase the loss of potassium from erythrocytes during prolonged incubation (Table 1). In agreement with previous reports on human cells[11], the potassium loss from irradiated rat erythrocytes was accelerated at low temperatures (Table 1), where active ion transport is much reduced[12]. However, addition of 1 mM ouabain (to inhibit active transport) failed to alter the effects of X-irradiation on potassium retention, either at 4° or at 37° C (Table 1).

The loss of potassium from irradiated erythrocytes at low temperatures remains unexplained. It was not accompanied either by hæmolysis or by loss of acid-soluble ribonucleotide bases. We have found that this loss is reversible, for when irradiated cells (60 kr.) were pre-incubated at 4° C for 20 h and then incubated at 37° C for another 4 h, their potassium content increased from 26 to 66 per cent of the original content. This re-accumulation was completely inhibited by 1 mM ouabain (Table 1). It was also noted that pre-incubation at 37° C for 4 h was sufficient to prevent excess loss of potassium from irradiated erythrocytes during subsequent incubation at 4° C. X-irradiation apparently destroys some component of the erythrocytes which they can repair or replace during incubation at 37° C but not at 4° C. However, the nature of this component has not yet been identified.

Influence of Soil Organic Matter on the Entry of Cæsium-137 into Plants

Interest in the behaviour of cæsium in soils has been aroused by the presence of the long-lived nuclide, cæsium-137, in world-wide fall-out. It is well established that in temperate climates the fixation of cæsium in clay minerals causes it to be little absorbed by plants from mineral soils[1], although it has been shown that in some tropical soils the degree of fixation is much less[2]. Thus, in general, contamination of the Western diet with cæsium-137 has been considered to depend predominantly on the levels of the recent deposition of world-wide fall-out[3].

However, when the rate of fall-out decreased after the middle of 1959 the activity of cæsium-137 in milk from many areas decreased to a lesser extent than would be expected on this basis[4–6]. These observations suggest that in such pastures cæsium-137 may remain available to plants for considerable periods after deposition. This may be due to the retention of cæsium-137 in the plant base zone[7] or to fixation in the soil under these conditions being considerably less than had hitherto been thought. As part of an investigation of this question we have examined the uptake of cæsium-137 by ryegrass from pasture soils.

Soil samples to a depth of 10 cm were collected from permanent pastures at five sites in Britain where varying levels of cæsium-137 had been observed in milk. A tropical soil was included in the experiment for comparison. Some characteristics of the soils are shown in Table 1; the cation exchange capacities of clay and organic matter were determined from measurements made before and after the organic matter had been destroyed by hydrogen peroxide.

The soils were uniformly contaminated with cæsium-137 and sown with perennial ryegrass, the foliage of which was gathered and analysed at regular intervals. The uptake of cæsium-137 between 10 and 26 weeks after sowing for two experiments is given in Table 1. The results are shown both in terms of the amount of cæsium-137 absorbed per pot and the uptake per g of plant tissue, since there were considerable differences in the yields on different soils. These were especially marked in the second experiment, which was conducted largely during the winter in a greenhouse with limited heating and supplementary illumination. Between soils the uptake of cæsium-137 varied by factors of up to about 20, when the results are expressed on either basis.

Previous work[8,9] suggested that the availability of cæsium is governed by the content of clay and exchangeable potassium. However, no simple relationships were apparent in the present results; the correlation coefficients (9 d.f.) were: ^{137}Cs uptake and percentage clay, $r = -0{\cdot}47$; ^{137}Cs uptake and exchangeable potassium, $r = -0{\cdot}51$.

The content of organic matter varied widely between the soils, and there is evidence of a greater availability of cæsium-137 in peaty soils[10]. The effect both of the percentage organic matter content and the cation exchange capacity (C.E.C.) of the organic matter on the uptake of cæsium-137 was therefore examined. The following correlation coefficients were obtained: ^{137}Cs uptake and percentage organic matter, $r = 0{\cdot}94$; ^{137}Cs uptake and C.E.C. on organic matter, $r = 0{\cdot}95$.

Both coefficients are significant at the 0·1 per cent level. It is suggested that these relationships reflect the fact that, when organic matter is responsible for a large fraction of the total exchange capacity of the soil, the adsorption and subsequent fixation of cæsium-137 on the clay minerals are much reduced. Eagle[11] has demonstrated a similar relationship between the organic matter content of soil and the availability of potassium, such that the greater the organic matter content the higher the level of exchangeable potassium.

Table 1. Uptake of Cæsium-137 by Perennial Ryegrass from Different Soils
(Values adjusted to a level of 1 μc./g soil)

Soil: Dominant clay mineral	(1) Mica	(2) Vermiculite	(3) Mica	(4) Vermiculite	(5) Montmorillonite	(6) Kaolin
Clay %	12·8	18·0	22·2	11·8	15·2	57·8
Organic matter %	9·95	4·62	2·74	1·95	1·66	1·30
Cation exchange capacity (m.equiv./100 g soil)						
Clay	7·7	12·0	11·2	9·4	19·7	30·5
Organic matter	27·1	15·2	11·0	8·4	0·7	1·0
Exchangeable potassium (m.equiv./100 g soil)	0·19	0·20	0·28	0·15	0·32	3·00
Ryegrass: 10–26 weeks after sowing						
Experiment I						
Yield per pot (g dry weight)	9·27	7·77	12·67	5·71	13·41	31·26
^{137}Cs uptake (mμc. g dry weight)	1,983	1,077	621	1,003	89	89
^{137}Cs uptake (mμc./pot)	18,380	8,340	7,850	5,720	1,200	2,770
Experiment II						
Yield per pot (g dry weight)	5·48	3·62	7·18	—	5·52	13·80
^{137}Cs uptake (mμc./g dry weight)	2,930	1,000	718	—	83	77
^{137}Cs uptake (mμc./pot)	16,060	3,630	5,160	—	460	1,050

Because of the slow downward movement of cæsium-137 in soil[12] it is, therefore, to be expected that shallow-rooted grasses will absorb the nuclide relatively freely from the cumulative deposit when the organic matter content of the upper soil layers is high. This frequently occurs in permanent pastures of cool temperature regions.

I thank Dr. R. Scott Russell for his advice during the course of this work.

BIOLOGY

Cyclical Behavioural Activity in the Pregnant Golden Hamster (*Mesocricetus auratus* Waterhouse)

In an examination of the behaviour of pregnant hamsters, cycles of activity have been found which are comparable to those seen in the non-pregnant female during the œstrous cycle. Animals were watched for an hour each day in their home cages. Observations were made under red lights half an hour after the lights went out on a 12 h/12 h reversed light cycle. At each minute during the watch, the activity in which the animal was engaged at that time and also its position in the cage were recorded. The vaginal cycles of the females were followed by a modified smear technique which depends on changes in the viscosity of the vaginal mucus[1].

The most commonly occurring categories were sleeping and presence in the nest, which are not wholly dependent on one another, for though sleeping only occurs in the nest other activities, such as grooming, are also commonly performed there. Sleeping also increases significantly during pregnancy, but the time spent in the nest does not. Both these measures show significant variation in the non-pregnant animal during the four-day œstrous cycle. Similar cycles have been obtained with activity wheels[2,3].

These measures also show cycle variations during pregnancy with significant falls from days 4 to 5 and 9 to 10, but not on other days (conception takes place on day 1). Preliminary results from activity wheel studies also suggest that peaks of activity occur on these days[3].

The sleeping scores for days 1, 5 and 10 were also compared with the means for the intervening or succeeding days. The probabilities are as follows:

Day 1, v. mean of days 2–4	$P = < 0{\cdot}01$
Day 5, v. mean of days 2–4	$P = < 0{\cdot}01$
Day 5, v. mean of days 6–9	$P = < 0{\cdot}01$
Day 10, v. mean of days 6–9	$P = < 0{\cdot}05$
Day 10, v. mean of days 11–13	$P = < 0{\cdot}05$

(2-tailed Wilcoxon matched pairs signed-ranks test)

Another day of high activity might be expected about day 13 or 14. However, by this time the placental hormone output may be relatively more important. Ovariectomy between the ninth and thirteenth days of pregnancy induces abortion in the hamster, but pregnancy can be maintained in spayed females with œstrogen and progesterone[4]. Further, the mean time spent sleeping per watch is higher in the latter half of pregnancy than in the first 8 days (P, 0·03, two-tailed sign test).

Mating during pregnancy has been reported in the hamster[2,5] and the frequency of occurrence tends to show a 4–5 day period[5]. Similar observations have been made on the rat[6,7] and mouse[8–10].

Cycles of vaginal cornification have been reported in a pregnant rat[6]. Though smears were followed through pregnancy in the present investigation no cyclic changes

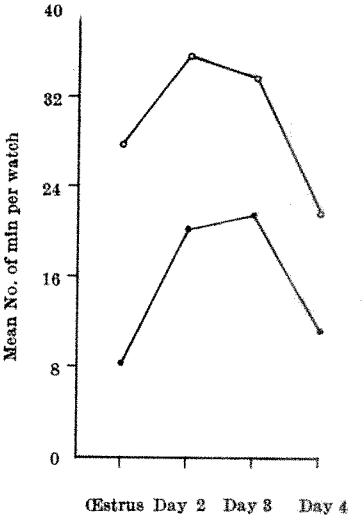

Fig. 1. Mean time spent sleeping (solid circles) and in the nest (hollow circles) for 20 non-pregnant females followed through the œstrous cycle. For both measures, days 1 and 2 and days 3 and 4 differ significantly. In each case $P = < 0{\cdot}01$ (2-tailed Wilcoxon matched pairs signed-ranks test)

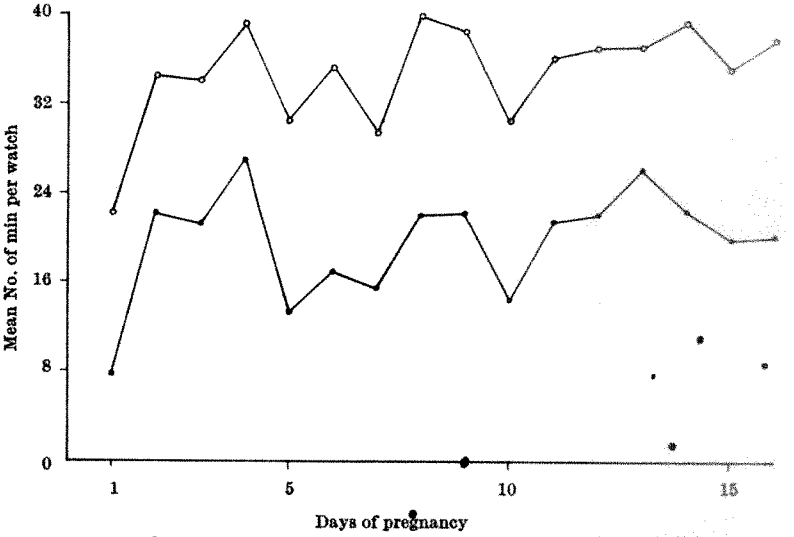

Fig. 2. Mean time spent sleeping (solid circles) and in the nest (hollow circles) for 16 animals followed through pregnancy. The fall in both measures from days 4 to 5 and 9 to 10 is significant ($P = < 0{\cdot}05$)

were seen, but the method used may not be sensitive to minor changes.

In 1930 Swezy and Evans[11] reported that cycles of oogenesis in the rat ovary were not interrupted by pregnancy and that small corpora lutea were formed on the 5th, 10th, 14th and 18th days of pregnancy. Apparently this observation has never been confirmed. However, more recently Zeiner[12] has shown that the gonadotrophic content of the pituitary of the pregnant rat tends to show peaks on the days when œstrus would be expected had mating not taken place.

In the light of Harris and Levine's suggestion[13] that the female central nervous system, and therefore the endocrine system, is inherently cyclic, it is interesting to note that cycles are only partly suppressed during pregnancy.

I thank Prof. A. S. Parkes, Prof. R. A. Hinde and Dr. R. V. Short for much helpful advice and discussion, and acknowledge a research studentship from the Department of Scientific and Industrial Research.

Chloroform Sensitivity of Mice

We, and many of our colleagues, did not appreciate the danger of chloroform to adult male mice until the following accident happened in our animal house. Our mouse population included two pure strains, one albino (*A.SW*), and one brown (*CBA-p*). There were breeding pairs with litters and non-mated adult stock mice, all in cages kept close together. We found two adult male brown mice dead one morning, and several others apparently very ill. Throughout the following week other mice were affected until our entire stock of adult male brown mice had died.

At first some infection was suspected, but bacteriological examination was negative, and only the adult male brown mice were affected. Post-mortem examination showed that the kidneys were pale and had a granular appearance. Histological sections showed that the renal tubules were necrotic and filled with eosinophilic material.

Shortly after recording these findings we learned that chloroform is a specific poison to adult male mice in very low concentrations, although albino males are somewhat more resistant. Rats had been killed with chloroform in the same room, about 20 ft. from where our mice were kept. This pattern is essentially the same as that described by Hewitt[1], that is, the production of severe renal damage in adult male non-albino mice with the sparing of all albino mice, and female and unweaned non-albino mice (both male and female).

Effect of Gibberellic Acid on the Growth and Multiplication of Some Soil Micro-organisms and Unicellular Green Algae

Since gibberellin has been isolated, results of its effect on the growth of higher plants have accumulated. However, little is known with regard to its influence on the growth and reproduction of lower plants.

Experiments utilizing bacteria have shown that no stimulation of growth or multiplication was found on introducing gibberellic acid into the culture media[1–3]. However, on applying the acid or 'Gibrel' (potassium salt of the acid) in the soil certain biochemical processes become more active, such as ammonification, nitrification, denitrification, sulphate reduction, nitrogen fixation, and the decomposition of other organic compounds[4–6]. No stimulation was observed when gibberellic acid was introduced into a pure culture of *Rhizobium trifolii*, strain 157 (ref. 7), but a significant increase in the growth of inoculated leguminous plants has been obtained when the acid was applied[8,9].

In most cases gibberellic acid has a neutral effect on fungal growth and reproduction[3,10,11], except that it inhibited spore formation of *Claviceps purpurea*[13] and some species of Basidiomycetes[12].

In concentrations of 0·1–10 mg/l. the acid has a stimulating effect on the growth of species of green alga[3,14–17], while concentrations of 100–400 mg/l. stimulate the growth of protonemata of some mosses[18–20]. The effect decreases with the increase of the acid concentration.

A normalization of growth was noted when plants infected by certain viral diseases were treated with gibberellic acid[21], but the virus itself was not affected by the acid[22].

Table 1. Effect of Gibberellic Acid on the Growth and Reproduction of Some Species of Unicellular Green Alga as shown in Numbers (millions) of Cells per ml. of Solution

Species	Concentration of gibberellic acid (mg/l.)					
	0	1·0	5·0	10·0	15·0	20·0
Chlorella vulgaris	7·1	8·4	6·9	3·5	4·2	4·5
Chlorella pyrenoidosa	9·4	11·2	9·9	7·2	6·8	6·4
Scenedesmus obliquus	4·3	5·1	4·2	6·6	3·7	4·2
Scenedesmus quadricauda	2·1	4·3	—	5·0	3·3	3·0

The experiment was conducted in Knop's solution, on a shaker, at 27° C, for 10 days, under constant illumination of daylight lamps of 3,000 lux.

With the view of finding microbial test objects to be utilized in the identification of natural growth stimulators the effect of gibberellic acid was tested on the growth and multiplication of 52 strains of soil microbes comprising 31 species of bacteria, 7 species of actinomycetes and 4 species of unicellular green algae.

Experiments with bacteria and actinomycetes were carried out by means of the cup-diffusion technique. In the case of algae, a liquid solution under constant illumination was used.

The acid was tested in the following concentrations: 0, 0·5, 1·0, 2·0, 5·0, 10·0, 15·0, 20·0, and 50·0 mg/l.

With the exception of two strains of *Azotobacter chroococcum* and *Actinomyces coelicolor*, the tested microbes did not react to the acid. Stimulation of growth and pigmentation was noted with *Az. chroococcum* strain 12 and strain 22; but this does not depend on the concentration of the acid. In the case of *Act. coelicolor* an increase of pigmentation with no stimulation of growth was observed.

Low concentrations of gibberellic acid stimulated the multiplication of all species of alga tested (Table 1). The maximum effect on *Chlorella* was obtained in a concentration of 1 mg/l., which then declined with the increase of the acid concentration. In the case of *Scenedesmus*, the maximum growth was noted in a concentration of 10 mg/l., and again it decreased with the in-

crease of the acid concentration. It appears that both species of *Scenedesmus* are more resistant to higher concentrations of the acid than those of *Chlorella*.

Toxicity of Captan Analogues to Oat Powdery Mildew

The fungicides captan (*N*-(trichloromethylthio)tetrahydrophthalimide) and phaltan (*N*-(trichloromethylthio)-phthalimide) are about equally toxic to *Alternaria tenuis* Nees and *Neurospora crassa* Shear and Dodge[1], but differ in toxicity to powdery mildews. Captan, for example, fails to control apple mildew (*Podosphaera leucotricha* (Ell. and Everh.) Salm.), but phaltan has been reported[2,3] to be effective against rose mildew (*Sphaerotheca pannosa* (Fr.) Jaczew.). This difference in effect is surprising because both fungicides contain the —$SCCl_3$ group which is generally considered to be responsible for the toxicity of captan[1], and the —CO.NX.CO— grouping which has also been suggested as a toxophore[4]. Powdery mildew spores have a high lipid content[5] and phaltan is more fat-soluble than captan[1]. The greater toxicity of phaltan to powdery mildews may therefore be due to easier penetration into the spores.

The importance of lipid solubility for powdery mildew fungicides was examined by testing captan, phaltan and five structurally similar analogues against *Erysiphe graminis* DC. ex Mérat on oats under glasshouse conditions. The analogues showed a wide range of lipid solubility; their purification and physical properties have been described elsewhere[1]. The compounds used were:

(*A*) *N*-(trichloromethylthio)tetrahydrophthalimide (captan)

(*B*) *N*-(trichloromethylthio)phthalimide (phaltan)

(*C*) *N*-(trichloromethylthio)hexahydrophthalimide

(*D*) *N*-(trichloromethylthio)-4-methylhexahydrophthalimide

(*E*) *N*-(trichloromethylthio)-4,5-dimethyltetrahydrophthalimide

(*F*) *N*-(trichloromethylthio)-3,6-endoxohexahydrophthalimide

(*G*) *N*-(trichloromethylthio)-4,5-epoxyhexahydrophthalimide

The compounds were prepared for test by dissolving in acetone then adding an aqueous solution of 'Ethylan CP', a non-ionic wetting agent (concentration of compound between $2{\cdot}5 \times 10^{-4}$ and $1{\cdot}0 \times 10^{-3}$ M; wetting agent, 0·0025 per cent; acetone, 2 per cent). The first fully expanded leaves of oat seedlings (var. 'Black Supreme') were dipped in the resulting solutions or suspensions, maintained at 30° C to ensure complete wetting. It was found that the chemically determined[1] deposits on the leaves, after drying, varied considerably according to the physical properties of the compounds. Thus at concentrations of 10^{-3} M, the solution of (*C*) gave a deposit of 0·35 μg/cm² of leaf surface, the suspension of (*A*) gave 4·2 μg/cm², and the suspension of (*D*), which contained large platelets, gave up to 31 μg/cm². This effect illustrates the error of assuming equivalent leaf retention after dipping in formulations of different compounds at the same tank concentration. Deposits of the same order of magnitude (up to 2 μg/cm²) were obtained by adjusting the concentrations of the compounds in the solutions or suspensions.

The compounds were tested for eradicant properties as follows. First, fully expanded oat leaves were inoculated by a standardized procedure of dusting with conidia of *E. graminis* from sporing infections maintained on oat seedlings. The compounds were applied by dipping the leaves 48 h after inoculation. The plants were left on the glasshouse bench arranged in randomized blocks and the mildew lesions which developed on both surfaces were counted 10–14 days later. Each treatment was replicated eight times and there was no evidence of phytotoxicity. For comparison, an emulsifiable concentrate of dinocap (2-(1-methyl-*n*-heptyl)-4,6-dinitrophenyl crotonate) was applied; deposits were determined by the method of Skerrett and Baker[6]. Inoculated untreated leaves and inoculated leaves dipped in acetone-wetter solutions were included in each test. Eradicant action was assessed from the reduction in the number of lesions per 10 cm of length of leaf upper and lower surface.

The lipid solubility of each compound was assessed from its oleyl alcohol/water partition coefficient determined previously[1].

The levels of deposit, the reductions in infection, and the water solubilities and partition coefficients of the compounds are shown in Table 1. Only compounds (*C*), (*F*) and (*G*), which had the highest water solubilities, showed significant eradicant effects. Compound (*C*) gave an excellent control, a deposit of 0·21 μg/cm² showing a toxic action not significantly different ($P = 0{\cdot}05$) from that of a deposit of dinocap of 0·75 μg/cm². Preliminary trials have shown compound (*C*) to be similarly effective as an eradicant of *Oidium* sp. on marrow.

Table 1. Eradicant Control of Oat Powdery Mildew by Analogues of Captan

Compound	Deposit (μg/cm² leaf)	Reduction of infection %	log $(x+1)$*	Water solubility (moles $\times 10^{-6}$/l.)	Oleyl alcohol–water partition coefficient
A	1·1	12	2·00	30	140
B	1·8	5	2·04	11	1,350
C	0·21	98	0·56	354	250
D	0·21	3	2·05	28	700
E	1·7	24	1·94	33	850
F	0·27	74	1·49	663	45
G	0·56	52	1·75	348	7
Dinocap	0·75	95	0·79	—	—
Inoculated leaves dipped in acetone/wetter solution			2·06		
Inoculated untreated leaves			2·07		
Least significant differences ($P = 0{\cdot}05$)			0·24		
($P = 0{\cdot}01$)			0·32		
($P = 0{\cdot}001$)			0·42		

* Where x is the number of lesions per 10 cm length of leaf.

The compounds were also tested as protectant fungicides by dipping oat leaves and allowing the deposit to dry before inoculation with *E. graminis*. At the concentrations of (*A*)–(*G*) shown in Table 1, none of the compounds gave a significant reduction in infection; dinocap at 0·75 μg/cm² gave 96 per cent reduction in infection. At higher levels of deposit, compound (*C*) gave control comparable with dinocap, deposits of 0·34 and 0·43 μg/cm² giving reductions in infection of 74 and 96 per cent respectively.

The toxicities of compounds (*A*)–(*G*) either as eradicants or as protectants to *E. graminis* follow a different pattern from their fungistatic activities to *N. crassa*[1]. There was no evidence that lipid solubility, as assessed from the oleyl alcohol/water partition coefficient, was directly correlated with either protectant or eradicant toxicity to *E. graminis*; thus phaltan (compound (*B*)), though tested at a higher level of deposit than the other compounds, was no more effective than captan either as an eradicant or as a protectant oat mildew fungicide. In fact the most effective eradicants ((*C*), (*F*) and (*G*)) had high water solubilities though wetting injury to the mildew[7] may have contributed to the effects obtained.

On the assumption that captan and its analogues have the same mode of action, it would seem that a ratio of water solubility to lipid solubility similar to that shown by (*C*) is necessary before toxicity is achieved.

We thank Dr. A. R. Kittleson, Esso Research and Engineering Co., New Jersey, for samples of the captan analogues.

Sensitivity to Dinitrophenol of Potassium Absorption in Carrot Root Tissue Cultures

In 1954, Steward and Millar[1] reported that the absorption of cæsium ions by carrot root tissue was inhibited by dinitrocresol, and that after tissues had been stimulated to rapid growth in the presence of coconut milk they were more sensitive to the inhibitor than were slowly growing cultures. Steward concluded that the rapidly growing tissues consisted mainly of meristematic cells while the slowly growing tissues comprised mainly vacuolated cells. On this assumption he explained the differing sensitivity to uncoupling agents of the tissue in its two conditions by the suggestion that salt absorption into the cytoplasm of plant cells is more dependent on oxidative phosphorylation than is the subsequent transfer of ions into vacuoles. The experimental data provided by Steward and Millar[1] and by Millar[2] in support of this important conclusion are, however, rather complicated and difficult to interpret. Furthermore, Arisz[3] claimed that chloride absorption into the cytoplasm of *Vallisneria* leaf cells is less sensitive to dinitrophenol than is its accumulation into vacuoles. In view of these considerations, it seemed desirable to examine the situation further and we wish to report some observations on the sensitivity to dinitrophenol of potassium absorption in rapidly and slowly growing carrot tissue cultures.

The cultures were grown in liquid media in the manner described by Caplin and Steward[4] except that in our experiments the coconut milk used to stimulate growth had previously been desalted. The advantage of this modification is that it makes possible the examination of absorption from media of known ionic composition. Sutcliffe and Counter[5] directed attention to the importance of this in interpreting the results of observations on the effects of salt concentration on uptake by carrot tissue cultures. The growth-promoting qualities of desalted coconut milk when added to a basal medium of adequate salt composition are 10–20 per cent less than those of whole coconut milk, but cell counts and anatomical investigations have indicated that the tissue cultures obtained in this way are essentially similar to those used by Steward and his collaborators in their investigations.

Various concentrations of dinitrophenol were added to the nutrient medium and the effect on fresh weight increase and potassium content of slowly and rapidly growing carrot tissues is shown in Table 1.

Table 1. Potassium content and fresh weight of 5 replicate batches of carrot root explants grown for 21 days at 23° C in a nutrient medium ± desalted coconut milk (D.C.M.) containing a series of concentrations of 2,4-dinitrophenol. Initial fresh weight 2·43 mg and initial potassium content = 0·04 μequiv. per explant

Treatment	Fresh weight mg per explant (± *S.E.*)	Increase in wt. (mg)	Potassium content μequiv. per explant (± *S.E.*)	Increase in potassium content (μequiv)	μequiv. per g fresh wt.
Basal

10^{-5} M DNP	40·64 ± 1·41	38·21	2·21 ± 0·14	2·17	54
10^{-4} M DNP	Toxic				

The results of this experiment show that tissues cultured for 21 days in the presence of coconut milk increased in fresh weight about twenty-seven times, while those cultured in a basal medium had increased by only four to five times. Although the rapidly growing cultures absorbed about three times as much potassium per explant as did the slowly growing cultures, the amount, when expressed on a fresh weight basis, was only about one-half owing to the more rapid absorption of water. This effect of rapid growth in lowering the apparent concentration of salt in tissue-cultured cells has previously been noted by Steward and Millar[1], and by Sutcliffe and Counter[5], but the magnitude of the effect seems to vary considerably from one experiment to another.

Concentrations of 10^{-7} M and 10^{-6} M dinitrophenol did not significantly affect growth or potassium content in either rapidly or slowly growing tissues under the conditions of the present experiment. Concentrations of 5×10^{-6} M and 10^{-5} M caused significant inhibition of both growth and potassium content. There appeared to be a slightly more pronounced effect on potassium content than on growth, particularly at the higher concentration of dinitrophenol. The rapidly growing cultures seemed to be slightly more sensitive to the inhibitor than the slowly growing ones, but the difference was not statistically significant. 10^{-4} M dinitrophenol was toxic to both rapidly and slowly growing cultures.

The sensitivity of carrot tissues to dinitrophenol has been found to vary somewhat on different occasions. In another experiment, for example, 10^{-5} M dinitrophenol was found to be toxic to both rapidly and slowly growing cultures. Caplin[6] has reported in some detail the variability in growth of carrot tissue cultures, and we have some evidence that variation in sensitivity to dinitrophenol may be related to growth potentialities.

The experiments described here differ in design from those of Steward and Millar[1] in that in our experiments the inhibitor was supplied for the whole of the culture

Table 2. Potassium content and fresh weight of 4 replicate batches of carrot root explants grown for 11 days at 23° C in nutrient media ± desalted coconut milk to which a series of concentrations of 2,4-dinitrophenol was added. Explants were then collected after 14 days. Initial fresh weight 2·63 mg, and initial potassium content 0·05 μequiv. per explant

Treatment	Fresh weight		Potassium content		
	Mg per explant (± S.E.)	Increase in wt. (mg)	μequiv. per explant (± S.E.)	Change in potassium content (μequiv.)	μequiv. per g. fresh wt.

period. In other experiments, following Steward and Millar[1], we have supplied dinitrophenol for only a part of the growth period. In one experiment, the results of which are presented in Table 2, tissues were allowed to grow for eleven days in a nutrient medium in the presence or absence of coconut milk and then dinitrophenol was added at a series of concentrations. Fresh weight and potassium content were determined (*a*) initially, (*b*) after the preliminary eleven days of culture, and (*c*) at the end of the fourteen-day experimental period. The growth of the control tissues in both the basal and coconut-milk-supplemented media was much less than in the first experiment described above. This can be partly, but not entirely, accounted for by the shorter growth period employed. As in the earlier experiment (Table 1), the fresh weight attained in the rapidly growing cultures was about five times that attained in the basal medium. The potassium content per explant in the control cultures after fourteen days was lower than that attained after twenty-one days in the first experiment. The amount of potassium expressed per unit of fresh weight was also lower in the case of the basal cultures, but in the rapidly growing cultures it was somewhat higher.

Dinitrophenol at 10^{-6} M was again without significant effect on the growth and potassium content of either type of culture. 10^{-5} M DNP inhibited growth and potassium uptake to a comparable extent, and the two tissues showed similar sensitivity to the inhibitor. As in the first experiment, however, slightly greater inhibitions occurred in the rapidly growing cultures. 10^{-4} M DNP prevented any significant increase in the fresh weight of both types of culture, and there was a decrease in potassium content during the three days in which the cultures were exposed to the inhibitor.

There seems to be little evidence from our experiments to support Steward and Millar's[1] contention that the absorption mechanisms themselves exhibit differing sensitivity to uncoupling agents in rapidly growing and slowly growing cultures. Growth itself is slightly more sensitive to inhibition in the rapidly growing than in the slowly growing cultures and this may account for the small differences in sensitivity of salt uptake observed in our experiments. At lower concentrations of DNP, growth and potassium content are reduced proportionately as dinitrophenol concentration increases.

MICROBIOLOGY

Sphæroplasts of *E. coli* obtained by the Lytic Enzyme isolated from Phage T_2

Sphæroplasts of *E. coli B*, obtained by treatment of cultures with 'ghosts' of phages, present an incomplete medium for the reproduction of the virus[1].

This incompleteness of sphæroplasts is determined by the disturbance of the synthetic processes of intact cells[1–3], which are probably connected with the increased permeability of 'ghost' sphæroplasts[4]. However, it is not clear which structures of the phage membranes provoke the disturbance of cellular permeability.

Our work was aimed at elucidating the following: (*a*) characterization of sphæroplasts, obtained by the treatment of *E. coli* cells with the lytic enzyme of the phage, as a system for virus reproduction; (*b*) investigation of the permeability of the cells during treatment with the lytic enzyme of the phage.

For the isolation of the lytic enzyme of bacteriophages concentrated phage T_2 ($2–3 \times 10^{13}$ particles/ml.) was freeze-thawed 15 times (−78° C and 37° C) in the presence of DNase (renal) 35 μg/ml. The preparation was purified from intact particles and sub-structures of phages by two rounds of centrifugation: 1 h at 18,000*g* (centrifuge *CLR*–1) and a second centrifugation of the supernatant fluid 1 h at 105,000*g* (Spinco model *L*50).

As the lytic phage enzyme the supernatant fluid obtained after the second centrifugation was used. The residual phage in this fraction was $2–5 \times 10^5$ particles/ml.

In the experiments a 2-h culture of *E. coli B* or *B*/2 was used, grown with shaking in phosphate-buffer-broth (*p*H 7·2) to $2–3 \times 10^8$ cells/ml. The lytic activity was determined by measurement of the optical density of the mixture, consisting of 0·9 ml. of the culture washed in medium *M*9 and treated with chloroform, and 0·9 ml. of the corresponding dilution of the lytic enzyme. Measurements were made using a photoelectric colorimeter at E_{418} or on plates[7].

Sphæroplasts of *E. coli* were obtained in the *tris*-buffer (*p*H 8·2) with the addition of 0·03 per cent versene (EDTA) and 40 per cent of sucrose: the culture of *E. coli B*/2 washed in the *tris*-buffer was resuspended in one volume of the aforementioned mixture and 2 volumes of the lytic enzyme of phage T_2 were added. 15–20 min later the sphæroplasts were formed. The lysozyme sphæroplasts were obtained by Repaske's[8] technique. The method of 'ghost' sphæroplast production and infection of sphæroplasts by the π-factor has been reported before[1].

The permeability of sphæroplasts was determined by the yield of aldolase. The suspension of sphæroplasts was centrifuged for 10 min at 5,000 r.p.m. and in the supernatant fluid the aldolase activity was determined[6].

The lytic enzyme of the phage did not dissolve the living cells of *E. coli B* or *B*/2. The activity of the enzyme was revealed only after preliminary treatment of the cultures with chloroform or in the presence of EDTA (Fig. 1). In the presence of EDTA and sucrose the lytic enzyme of phage T_2 induced the conversion of cells of *E. coli B* or *B*/2 into spherical forms morphologically similar to lysozyme sphæroplasts.

It was found that sphæroplasts of *E. coli B*/2 induced by the lytic enzyme of phage T_2 were able to provide a medium for the reproduction of the virus after infection with the π-factor—obtained from phage T_2h (Table 1).

The yield of phages in these sphæroplasts was identical to the yield of phages demonstrated in the lysozyme sphæroplasts infected by the same factor.

In experiments on measurements of the yield of aldolase it was demonstrated that in sphæroplasts obtained from *E. coli B*/2 the permeability barrier for this enzyme is not disturbed and in this respect they are similar to the lysozyme sphæroplasts (Table 2).

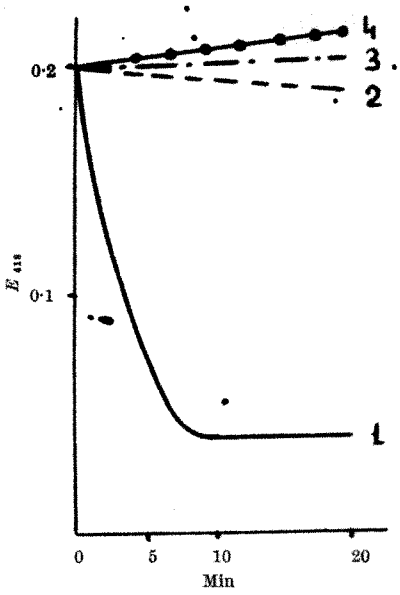

Fig. 1. Action of the lytic enzyme, isolated from phage T_2 on a living culture of *E. coli* B/2 and a culture treated by chloroform. (1) Culture treated with chloroform + enzyme; (2) culture treated with chloroform + medium; (3) living culture + medium; (4) living culture + enzyme

Hence the sphæroplasts obtained by the action of the lytic enzyme of the phage and by egg-white lysozyme are similar, and differ from the 'ghost' sphæroplasts which in these experiments, as in earlier experiments[1,4], were found to be unable to provide the reproduction of the virus, and this inability is related with the disturbance of the cytoplasmic membrane.

On the basis of these results and those published previously[1,4] it can be concluded that the so-called 'killing-effect' of phage T_2 is related to the lytic enzyme, and is unable in isolated form to induce disturbances of the permeability barrier. Probably the protein membrane of phage T_2 maintains besides the lytic enzyme a factor, acting similarly to EDTA or chloroform. This inference is a sequence to the fact that the ability of the 'ghosts' to dissolve the cell wall or to convert the bacteria in a sphæroplast in hypertonic media is realized in media without EDTA or chloroform. The isolated lytic enzyme of the phage is capable of producing similar effects only by the 'sensibilization' of cells with the aforementioned co-factors. On the other hand, it is logical to admit that the protein membrane of phage T_2, besides the lytic enzymes, is maintaining a factor which provides the 'killing-effect' by a sharp disturbance in the permeability of the cell. This factor may be a specific enzyme. The possibility that disturbance of the cell permeability barrier is produced by a mechanical perforation of the membrane in the irreversible phase of the adsorption of the phage particles on the bacterial cell must not be excluded.

Table 1. Reproduction of the Phage in Sphæroplasts obtained by Lytic Enzyme isolated from Phage Particles, Egg-white Lysozyme and Phage 'Ghosts'

$0{\cdot}8–1\times10^9$ bacteria treated with	Sphæroplast production (by the quantity of surviving bacterial cells) (%)	Phage titre after 30 min incubation of the mixture 1 ml. of sphæroplasts + 1 ml. broth	Phage filter after 30 min incubation of the mixture: 1 ml. of sphæroplasts suspension + 1 ml. π-factor
Lytic enzyme of the phage T_2	95·4	0	$2{\cdot}1\times10^4$
Egg-white lysozyme	99·9	0	$5{\cdot}5\times10^4$
Phage 'ghosts'	99·9	$1{\cdot}1\times10^2$	$6{\cdot}1\times10^2$

Table 2. Permeability of Sphæroplasts, obtained by Lytic Enzyme isolated from Phage Particles, Egg-white Lysozyme and Phage 'Ghosts'

$0{\cdot}8-1{\cdot}0\times10^9$ of cells treated with	Production of sphæroplasts (measured by the quantity of surviving cells) (%)	Release of aldolase in incubation media (in units of activity)
'Ghosts' of phages	99·9	288
Lysozyme of egg-white	99·9	0
Lytic enzyme of phage T_2	97·4	0

ENTOMOLOGY

High-intensity Flash Discharge as a Source of Radiant Energy for Sterilizing Insects

The possibility of using sterilized male insects to reduce the numbers of a pest species or even to eliminate it within a restricted area has assumed considerable importance since the successful application of this method by Baumhover *et al.*[1] against the screw-worm fly. Gamma-radiation is most frequently used to sterilize males, though lately chemo-sterilants are receiving increasing attention. Both these methods have drawbacks, especially in regard to safety aspects.

A paper by Nelson[2] on the chemical reactions which can be initiated by the heat from a high-intensity flash indicated that the possibility of using this form of radiant energy to sterilize insects was worth investigating, particularly since short-wave radiation in the ultra-violet region is known to damage proteins and nucleic acids and has been shown by Luria and Latarjet[3] to produce lethal mutations in bacteriophage.

Preliminary experiments were conducted with two species of insects: a small chalcid *Dahlbominus fuscipennis* Zett. that had been used previously in heat-sterilization studies[4], and the mosquito *Aëdes aegypti* (L.). The flash apparatus was an ordinary photographer's photo-flash that has a nominal output of 100 joules at 2,500 V. The insects were confined in cylindrical glass jackets encircling the envelope of the flash-tube so that the *D. fuscipennis* were held within 3 mm of the envelope and the *A. aegypti* within 7 mm.

Immediate mortality in the *D. fuscipennis* males was not recorded, but propagation of the survivors showed that 82–87 per cent were sterilized by a single flash. Two flashes killed or sterilized 100 per cent. Twenty-six per cent of the *A. aegypti* males were killed by a single flash and all the survivors were sterile.

Following the results a more refined flash apparatus was built to permit precise positioning of the insects in relation to the flash and in which the light output can be controlled. Experiments are now in progress to establish dose/effect relationships in *A. aegypti* and also to determine the longevity and competitiveness of the males that are sterilized. Similar experiments are planned with insect pests of stored food products.

Nervous Control of Flight Orientation in a Beetle

In a recent publication about the nervous control of dipteran flight, Wilson and Wyman[1] confirmed and extended previous observations of the absence of phase relationship between the movements of the wings and the nervous input to the muscles of insects possessing a fibrillar flight-motor. Their records show, however, that an increase in wing-beat frequency is accompanied by an increase in the frequency of nervous stimulation to the power muscles. In a concluding sentence, Wilson and Wyman suggest that frequency control may operate in the regulation of parameters like direction of locomotion.

In an investigation of flight orientation in the rhinoceros beetle, *Oryctes boas*, I have found that change of direction about the yaw axis is accompanied by a unilateral increase in frequency of the nervous input to the fibrillar flight muscles. Extracellular recordings have been obtained from the left and right members of all six pairs of fibrillar flight muscles during straight flight and yawing rotations of tethered beetles. The traces in Fig. 1 show the marked increase in frequency of the nervous input to the left muscle of a pair during yaw to the right induced by rotation of a striped cylinder.

Fig. 1. Extracellular recordings from left (upper trace) and right (lower trace) dorsal oblique muscles of *Oryctes boas*. (*a*) Straight flight; (*b*) yaw to the right

Stroboscopic photographs of tethered beetles executing yawing rotations show that yaw is achieved chiefly by a unilateral increase in amplitude of the wing stroke. Machin and Pringle[2] observed that an increased frequency of electrical stimulation to the basalar muscle of *Oryctes rhinoceros* resulted in an increase in the amplitude of oscillation of the muscle.

It is concluded that, during yawing rotations, the observed increase in frequency of the nervous input to the flight muscles of the appropriate side brings about a greater amplitude of oscillation of these muscles and so leads to a unilateral increase in amplitude of the wing stroke.

VIROLOGY

Antiviral Activity of Gliotoxin and Gliotoxin Acetate

During a search for antiviral materials, we found several *Penicillium* culture filtrates that inhibited the cytopathic effect of type 2 poliovirus MEF_1 in monkey kidney primary cell cultures. The antipolio activity of these filtrates was found to be due to gliotoxin and gliotoxin acetate.

Gliotoxin (I) (ref. 1) was first isolated in 1936 by Weindling and Emerson[2] and afterwards by others from culture filtrates of species of *Gliocladium* (?), *Trichoderma*, *Aspergillus* and *Penicillium*[3]. Its inhibitory activity towards bacteria, fungi and transplantable neoplasms is well known[4]. There has been no report of antiviral activity for gliotoxin. It is highly toxic for rodents[4] and as a result has no practical value as a therapeutic agent. For this reason we have not investigated its antiviral effect or mode of action, but we present this communication: (1) to demonstrate that methods are available for detecting potentially useful antiviral materials; (2) to report that this long-known compound exhibits antiviral activity; and thereby (3) to provide another tool for virus and chemotherapy research.

I

One monoverticillate *Penicillium*, strain *F*1072, had been isolated from a soil sample from Bath, Maine, U.S.A., and fermented aerobically at 26° C for 4 days in a medium containing glucose, acid-hydrolysed casein, enzymatically hydrolysed yeast, and sodium chloride. Crystalline material was first obtained from such culture filtrates by *n*-butanol extraction followed by alumina chromatography and countercurrent distribution. By modifying fermentation media and conditions, more potent culture filtrates were prepared. These filtrates were extracted with ethylene dichloride; and, after partitioning the dried extract between methanol and heptane, the active material was crystallized from the methanol fraction. The identity of this material with gliotoxin was established by physical and chemical comparison with an authentic sample.

Another monoverticillate *Penicillium*, *F*642, isolated from soil collected in Anvers, Belgium, yielded both gliotoxin and its monoacetate, which were differentiated chromatographically and separated by fractional crystallization. Both were active against type 1 (Mahoney) poliovirus.

Fermentation and isolation were assisted by agar diffusion assays and bio-autography with poliovirus type 1 (Mahoney) in *H.Ep.* 2 cells, using methods described by Herrmann and by Siminoff[5]. It was found that assays with *Micrococcus lysodeikticus* reflect poliovirus-inhibitory activity and that similar R_F values are obtained with samples developed in the same solvent system. Hence, agar diffusion with *M. lysodeikticus* was used to help guide fermentation, fractionation, and isolation because of its greater precision, speed and convenience. Poliovirus assays and bio-autograms were limited to confirmation of key samples.

Table 1 gives the antiviral spectrum of gliotoxin when tested at half-log serial dilutions with *H.Ep.* 2 and *KB* cell suspensions in plastic panels and with monkey kidney primary cell and *KB* cell monolayers in tubes. The test procedures in plastic panels have been described[6]. Similar methods were used for tests in tubes except that virus and drug were added simultaneously to 3–5 day monolayer cultures containing 1·0 ml. of maintenance medium (synthetic medium 199 for monkey kidney, Eagle's plus 10 per cent horse serum for *KB* cells). Gliotoxin was active against poliovirus, herpes and Asian influenza; but the end-points were more definite with poliovirus. Gliotoxin was inactive against rabies when added to a CVS infected mouse brain homogenate, and this mixture inoculated intracerebrally into healthy adult mice.

Chemotherapy trials were limited because of the poor solubility of gliotoxin and its toxicity for animals. The maximum tolerated single dose for mice was found to be 7·5 mg/kg intravenously (*N*,*N*-dimethylacetamide solution) and < 19 mg/kg intraperitoneally (sodium carboxymethyl cellulose emulsion). When gliotoxin was admini-

Table 1. Activity of Gliotoxin against Viruses in Cell Culture

* Toxic: minimal concentration of compound that produces a microscopically evident alteration in host cell morphology. Differences in toxicity may reflect the fact that tests were performed in two laboratories on various lots of cells.

† Active: minimal concentration of compound that inhibits the cytopathic effect of virus on host cells as indicated by microscopic examination.

‡ Lowest concentration tested with *KB* cells was 0·014 μg/ml.; with *H.Ep.* 2 cells, 2·0 μg/ml.

§ Inactive at highest concentration tested.

stered orally for twenty-one days, mice tolerated 10 but not 20 mg/kg/day (gum acacia suspension). Mice were challenged intracerebrally with 10 or 32 LD_{50} type 2 poliovirus (MEF_1), then treated orally with 5 or 10 mg/kg/day for 21 days starting 24 h after challenge. This treatment failed to protect the animals; it is not known whether virus-inhibitory gliotoxin-levels were achieved systemically with the suspension used.

CYTOLOGY

Chromosomes of X-ray-induced Giant Cells in Chinese Hamster *in vitro*

The description of giant cells in biological and medical reports is limited to morphology[1,2], biosynthesis[3,4] and cellular growth[5,6]. This communication describes the chromosome status of the giant cells induced by X-irradiation *in vitro*.

A 'near-tetraploid' cell sub-line of Chinese hamster (*Cricetulus griseus*)[7] with doubled stemline chromosome number (46) (ref. 8) was used for this work. Cells were grown on HUT–15 medium and incubated at 37° C in a humid atmosphere of 2 per cent carbon dioxide and air. They were X-irradiated at a dose of 1,500 r. with 250 kVp. X-rays (half-value-layer of the order of 0·9 mm copper) at a dose rate of about 110 r./min. Observations of chromosomes were made on each sample at intervals 24–144 h after irradiation. Cytological preparation involved colchicinization of cells at a concentration of 2 μg/ml. culture medium for 2 h, hypotonic treatment with 0·9 per cent sodium citrate for 30 min, fixation in acetic alcohol (1 : 3) for 1 h, air-dry technique, and staining with 2 per cent aceto-orcein.

The giant cells described here have a large number of chromosomes at metaphase. They were found to have approximately 92, 184, 368 or 736 chromosomes which appeared to be $8n$, $16n$, $32n$ or $64n$, respectively, since the cell sub-line was designated as 'near-tetraploid' (46 chromosomes). The percentages of giant cells obtained at different intervals after X-irradiation are listed in Table 1. The $8n$ cells in this culture reached 64 per cent by 48 h after X-irradiation. After 48 h, the $8n$ cells decreased and cells with higher ploidies ($16n$, $32n$, etc.) predominated. The $8n$–$64n$ cells accounted for approximately 80 per cent (74–84 per cent) of mitoses observed at each interval of 48–144 h after irradiation.

Table 1. Per cent Giant Cells induced by X-rays (1,500 r.) in Chinese Hamster *in vitro*

Hours after irradiation	Giant cells in polyploid forms* 4*n*	8*n*	16*n*	32*n*	64*n*
Control	99	1			
24	84	16			
30	76	24			
48	26	64	10		
72	20	54	18	8	
96	18	46	26	10	
120	18	40	26	14	2
144	16	30	28	20	6

* The values $4n$, $8n$, etc., are approximate only.

The formation of higher ploidies due to chromosome doubling of lower ploidies is known as endo-reduplication (endo-mitosis). Yu and Sinclair[9] pointed out that in the Chinese hamster cells the X-ray-induced polyploidization was due primarily to endo-reduplication. All the $8n$ cells

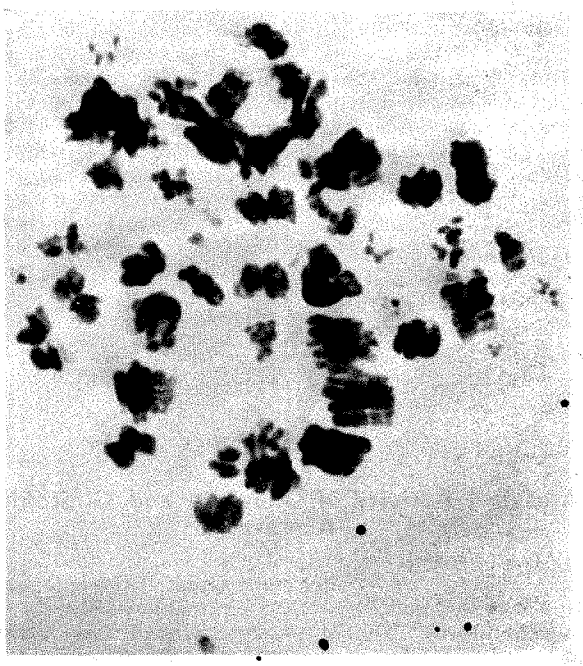

Fig. 1. An endo-reduplication cell. Each bundle consists of eight chromosomes

observed by them 24 h after irradiation were endo-reduplication cells with diplochromosomes. Levan and Hauschka[10] believed that the configuration of diplochromosomes at metaphase was the result of endo-reduplication. Endo-reduplication may occur several times without division of the cells, therefore each centromere observed at metaphase is associated with four chromatids (single endo-reduplication), eight chromatids (two endo-reduplications)[11], or even 16 chromatids (three endo-reduplications). For example, in the work recorded here, a giant cell observed 72 h after irradiation had bundles of eight chromosomes (16 chromatids), which indicated that endo-reduplication had occurred three times in succession, thus giving rise to $32n$ (Fig. 1).

In general, the X-ray-induced chromosome aberrations found in the giant cells were the same as those described in the literature. However, there is a type of aberration, the polycentric chromosome, found in the giant cells which has not yet been reported. Some fragments of the broken chromosomes resulting from X-irradiation may join at their broken ends to form a di- or poly-centric chromosome. Such a chromosome may duplicate itself through endo-reduplication resulting in two identical chromosomes (in this case, they are sister diplochromosomes). These two identical chromosomes may again join together at their same broken ends to form a bilaterally identically-symmetrical (BIS) chromosome; its right and left halves are, therefore, mirror images of each other. If a second endo-reduplication occurs before the cell enters mitosis, these BIS chromosomes will be reduplicated. Therefore, two identical BIS chromosomes will have been formed and will be seen at the next metaphase. Furthermore, BIS chromosomes may replicate themselves several times, for example, four identical BIS chromosomes may result from three endo-reduplications and be seen at the following metaphase (Fig. 2). Almost every giant cell ($16n$–$64n$) was found to have one or more BIS chromosomes. However, they may be di- or tetra-centric.

It is possible to interpret, particularly in this case, the meaning of nuclear growth of giant cells in relation to the occurrence of BIS chromosomes, and the appearance of diplochromosomes. When X-rays cause endomitosis, the cells may continue biosynthesis without division being recognized by their large size due to nuclear growth. The length of the nuclear growth period may be dependent on the time needed to complete endo-reduplication. If endo-reduplication should recur, the mitosis may appear much later. For example, cells with two and four identical BIS chromosomes have been found at 96 and 120 h, respectively, after X-irradiation. This suggests that induction of BIS chromosomes in giant cells by X-rays is not a spontaneous but a complex process involving a series of cytological mechanisms.

GENETICS

Blood Culture Method for the Study of Bovine Chromosomes

THE development of leucocyte culture techniques[1–3] has greatly facilitated the investigation of chromosome anomalies associated with various human disorders[4–9]. Chromosome investigations on domestic animals with similar disorders have been relatively rare, probably because the techniques used for the delineation of human chromosomes are often inapplicable. The most popular procedure for the cultivation of leucocytes involves the use of navy bean extracts both as a hæmagglutinating agent[1,3] and as a mitogenic agent[10,11]. Reports from various laboratories have indicated that phytohæmagglutinin M used for the separation of human leucocytes is ineffective on the erythrocytes of several domestic and wild animals[12–14]. The dextran method developed by Nichols and Levan for the separation of leucocytes from laboratory animals[15] has been extended successfully to some domestic and wild animals when the phytohæmagglutinin method has failed to provide adequate amounts of leucocytes for culture[12]. Neither the phytohæmagglutinin method nor the dextran method has been efficient enough for the separation of bovine leucocytes; consequently, investigators concerned with the investigation of bovine chromosomes have resorted to various agents such as fibrinogen[16] and ficoll[13] or to prolonged centrifugation[14,17] for obtaining leucocytes. In the course of our work on the chromosomes of cattle with lymphosarcoma we have developed a simple method which provides good preparations of bovine chromosomes. The method has also proved efficient for the investigation of somatic chromosomes of other domestic animals.

Venous blood, drawn aseptically into a syringe previously rinsed with 0·2 ml. of 1 per cent sodium heparin solution, was used in all experiments. The growth medium used for the cultivation of blood cells was Connaught's '*H*597', supplemented with 20 per cent inactivated calf

serum, 0·08 per cent sodium bicarbonate and potassium penicillin G at a concentration of 100 I.U. per ml.

9 ml. of growth medium, 0·5 ml. of phytohæmagglutinin M (Difco) and 1·0 ml. of whole blood were introduced into each 30 ml. capacity McCartney bottle. The blood was mixed with the medium by gently shaking the bottle before placing in the incubator at 38° C.

On the third day after setting up the cultures, 1·0 ml. of phosphate buffered saline (PBS) containing 100 μg of colchicine was released into each culture bottle in order to accumulate metaphase stages. After 6 h incubation with colchicine, the bottles were left at room temperature for 10 min after adding 20 ml. of distilled water to each bottle. The diluted medium was spun at 300 r.p.m. for 2 min in narrow 15 ml. capacity centrifuge tubes and the sedimented cells were fixed in fresh carnoy solution for 10 min. The sediment was dispersed by gentle aspiration with a Pasteur pipette and the suspension was centrifuged again as described before. The sedimented cells were re-suspended in 0·5 ml. of fresh Carnoy solution and two or three drops of this suspension were placed on each clean slide. The slides were air-dried before being stained with 2 per cent natural orcein or carbol fuchsin. The procedure for making permanent mounts was the same as that for human leucocytes.

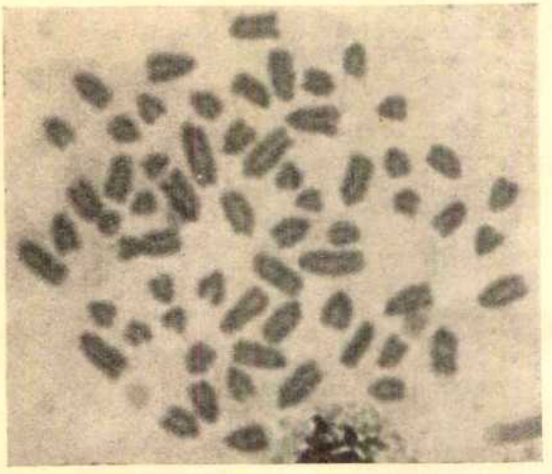

Fig. 1. Metaphase chromosomes of a normal cow. Air dried. Orcein stain. (× 2,000)

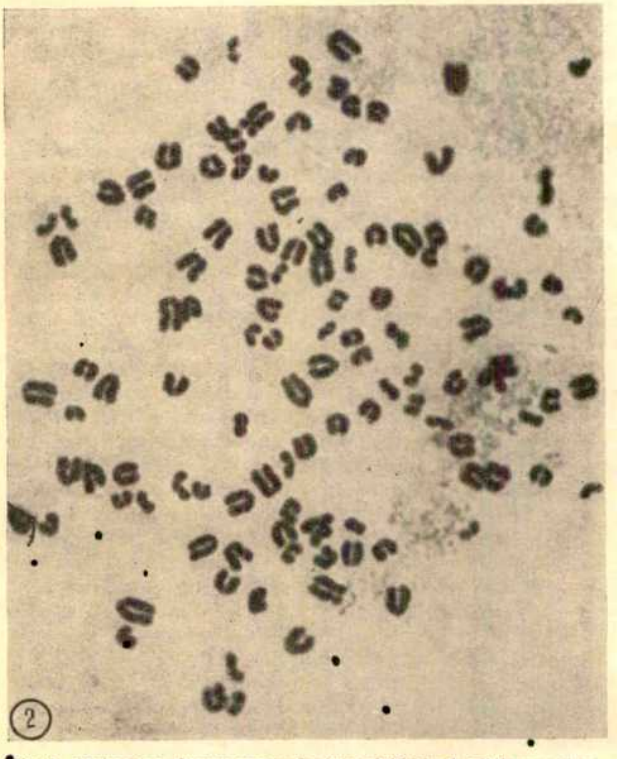

Fig. 2. Metaphase chromosomes of a tetraploid blood cell from a steer with lymphosarcoma. Air dried. Orcein stain. (× 2,000)

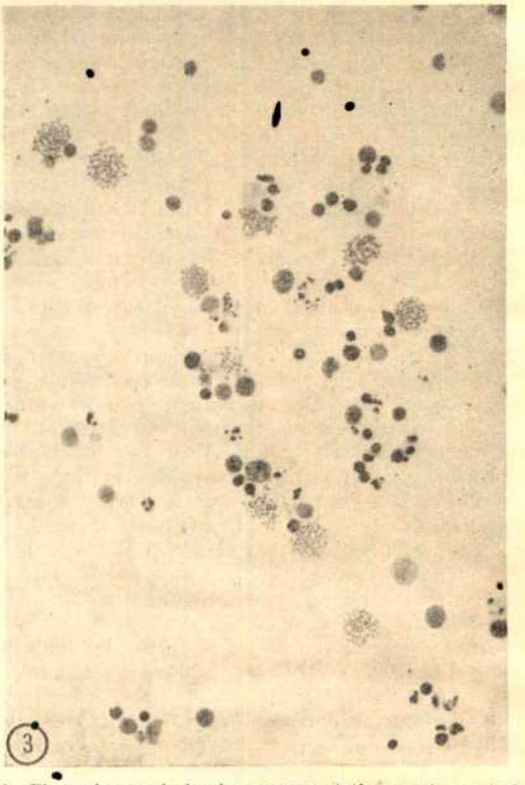

Fig. 3. Photomicrograph showing a representative area in an air-dried preparation from a blood culture of a normal cow. The blood was mixed with the medium and stored at room temperature for 6 h before incubation. Note the abundance of metaphase plates with well spread chromosomes. Orcein stain. (× 600)

Good chromosome preparations have been consistently obtained with this method from blood samples of normal as well as lymphosarcoma cattle (Figs. 1 and 2). Under our laboratory conditions a single culture of 1·0 ml. yields 30–50 well-spread metaphase plates for chromosome analysis (Fig. 3). Storing heparinized whole blood or blood samples mixed with the culture medium at room temperature, for up to 6 h before incubation, does not seem to affect the quality of chromosome preparations or the percentage of mitoses in the culture.

The addition of 2 volumes of distilled water to the medium before fixing the cells has proved adequate to lyse the erythrocytes in the culture. The ghosts of these erythrocytes are eliminated along with the discarded centrifugates before and after the addition of the fixative. We have tried both M and P fractions of phytohæmagglutinin obtained from Difco Laboratories as well as the crude extract produced by Wellcome Laboratories. Both Wellcome's phytohæmagglutinin and Difco's phytohæmagglutinin M have been equally satisfactory for metaphase spreads, although the latter in our hands tended to yield more mitotic stages per culture. We have also noticed that cultures incubated for 4 days are as good as those used after 3 days incubation, although incubation for more than 4 days has tended to reduce the percentage of mitoses.

This method of cultivation has also provided well-spread metaphase plates from blood samples of goats (Fig. 4), sheep and mink, although the fixed cells of sheep and mink had to be squashed in a drop of acetic acid in order to get good metaphase spreads (Fig. 5).

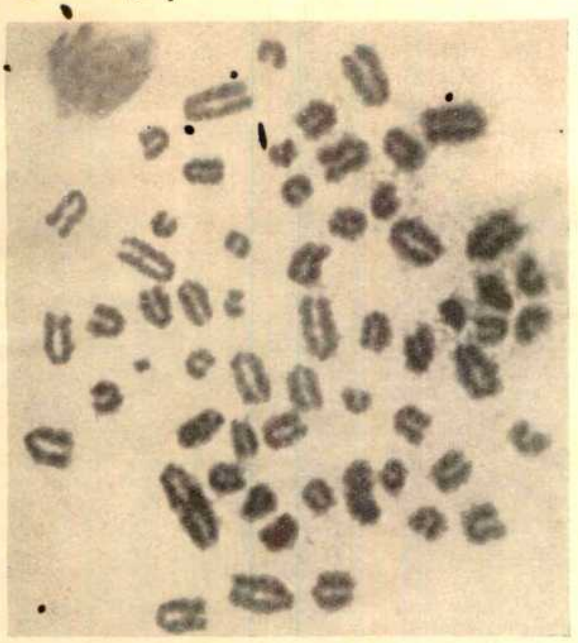

Fig. 4. Metaphase chromosomes of a male goat. Air dried. Orcein stain. (× 2,000)

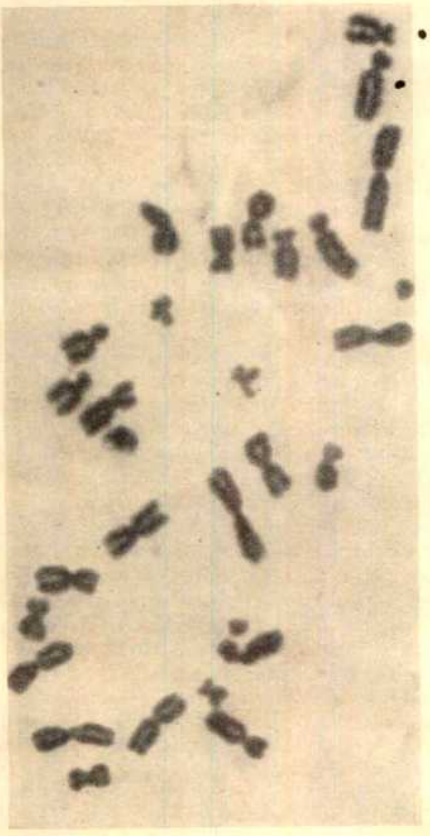

Fig. 5. Metaphase chromosomes of a female mink. Acetic acid squash. Carbol fuchsin stain. (× 2,000)

This culture is especially suitable for chromosome examinations on a large number of animals in a herd, since very little time and effort are required to set up cultures from the blood sample of each animal, and the results are comparable with those obtained by more involved techniques (see refs. 13, 14, 16, 17, 20). Furthermore, persons untrained in blood culture technique can release the blood samples into previously prepared bottles for shipment to the investigator for chromosome analysis.

This work was supported in part by the National Cancer Institute of Canada. We thank Dr. Lynette Keur and Mrs. Agnes Anderson for their assistance.

PSYCHOLOGY

Dream Deprivation: an Experimental Reappraisal

Dement[1], using the rapid eye movement method of dream detection, prevented subjects from dreaming on five successive nights by awakening them at the onset of each rapid eye movement period (REMP). The results included a steady increase in the forced awakenings necessary during the deprivation period, a marked increase in the percentage of dream time when subjects were allowed to sleep undisturbed and certain behavioural changes summarized as "anxiety, irritability, and difficulty in concentration". From a psychiatric point of view we felt the implications of this apparent 'need to dream' were significant. We therefore elected to carry out a dream curtailment of our own to assess any quantitative or qualitative psychic changes through continual observation and psychometric testing.

Two male graduate student subjects were screened for emotional and physical health. A large room equipped for normal daytime activities was provided and the subjects were continually observed by hospital volunteers in order to prevent any sleeping. The subjects were taken to the EEG laboratory at 10 p.m. nightly and allowed to sleep in adjacent, air-conditioned and sound-attenuated rooms. Cortical EEG and eye movements were recorded continuously on two 16-channel Grass electroencephalographs.

The subjects were allowed to sleep undisturbed for several nights while baseline recordings were obtained. During the following six nights, subjects were fully awakened at the onset of each rapid eye movement period. Usually awakenings occurred within 15–40 sec after the first eye movement burst. Following this dream (REMP) curtailment, the subjects were allowed to sleep undisturbed for two nights. As a control study, the same subjects returned to the laboratory and were awakened an equal number of times during non-REMPs for six nights. During both experiments, measurements were made nightly of total sleep, total dream and percentage dream times using the usual scoring method[2]. Psychometric studies, including one or more of the following tests, were carried out daily for both the deprivation and control experiments: M.M.P.I., Nowlis adjective checklist, Clyde mood scale, Stroop colour word test and digit span.

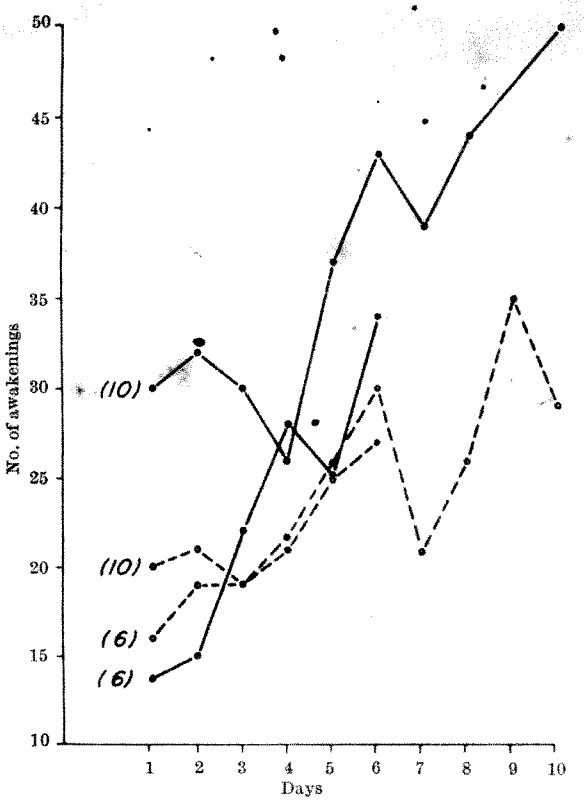

Fig. 1. Dream deprivation. ——, Subject No. 1; — — —, Subject No. 2. In brackets, No. of dream deprivation nights

Our results confirmed the previous findings of an unequivocal progressive increase in so-called 'attempts to dream' during the deprivation period. No such tendency occurred during the control awakenings. Our results also confirmed the finding of an increase in the percentage dream time during the recovery nights following the deprivation period. However, psychological testing and subject observation revealed only minimal psychic changes. These changes were as characteristic for the control as well as the deprivation period so that they could not be attributed to the dream curtailment itself.

We were then interested in increasing the number of deprivation nights from 6 to 10 to determine if the objective findings would increase proportionately and to again evaluate any psychic changes. In order to make the deprivation more complete, we decided to use a decrease in muscle tonus as a signal for awakening, as this decrease characteristically occurs just prior to, or concomitant with, the onset of a REMP[3,4]. Electromyographic leads were attached to the sub-mental region and the decrease in muscle tonus from this area was utilized as the awakening signal. Psychometrics were administered more often during the 10-day study, but otherwise the procedure was as before. The same two subjects were again used in order to (1) avoid the variable of comparing the effects of 10 nights versus six in different persons, and (2) because it was felt that a new set of control awakenings were not mandatory if the same subjects were used and the findings were similar.

As can be seen in Fig. 1, the number of awakenings required to prevent dreaming on the first and sixth nights is greater in the 10-night series than in the previous six-night study. Also, the total number of awakenings greatly increased, 51 awakenings being required with Subject No. 1 on night No. 10. In Table 2, the percentage dream time and percentage increase on recovery nights are listed. The increase in both these objective findings is attributed to the more complete deprivation afforded by the use of the EMG signal for awakening, and the increase in the length of the deprivation period. Psychological testing again revealed few significant changes and, although the testing and observation indicate that subjects were somewhat more affected by the longer experiment, there is little evidence that these changes are anything more than the result of sleep deprivation and the irritating accompaniments of the experimental situation.

Table 1. Six Night Deprivation Period

	Subject	No. of dreams	Dream time (per cent)	Increase dream time (per cent)
Baseline recording (av. of 3 nights)	1	4	20·3	
	2	4	22·7	
Recovery night No. 1	1	5	34·9	72·5
	2	4	31·8	40·0
Recovery night No. 2	1	4	30·8	52·0
	2	4	30·5	34·3
Control recovery nights	1	5	23·8	17·5
	2	4	19·6	−13·6

Table 2. Ten Night Deprivation Period

	Subject	No. of dreams	Dream time (per cent)	Increase dream time (per cent)
Baseline recording	1	6	20·0	
	2	5	20·1	
Recovery night No. 1	1	5	40·6	102·5
	2	4	36·0	78·6
Recovery night No. 2	1	5	32·6	62·4
	2	4	39·9	98·3

Subjects' dream time was normal when measured again one week after deprivation.

Subsequent to our work, Dement[5] deprived several additional subjects of dreams. All the subjects again showed the same objective findings of increased dream attempts during deprivation nights and percentage dream time on recovery nights. In addition, two of the subjects exhibited personality changes of a non-psychotic nature. Dement, himself, has questioned these results on the basis of 'Dexedrine' used in both of these subjects, a lack of controls, and a pre-existing schizoid behaviour pattern in one of these subjects.

In summary, our results agree with the previously reported findings of an increase in the number of awakenings necessary to prevent dreaming and an increase in the dream time percentage on the first recovery night, both findings being proportional to the amount of dream curtailment. Our results do not substantiate the hypothesis that psychic changes occur with deprivation of REMPs; however, in interpreting these results we realize there may be large variations in response from individual to individual. Subjects are permitted to experience only a few seconds of dreaming by using the EMG signal to indicate when awakening is required. One of the subjects consistently reported bizarre, vivid dreams of approximately 1-min duration when awakened after this signal. The other subject often reported fragmentary mentation and occasionally a brief, vivid dream when awakened. It may be possible that there is a compensatory acceleration of the dreaming process under conditions of deprivation so that within a few seconds there is substantial content. Thus this dreaming, brief as it is, may be sufficient to prevent significant psychic changes. This possibility is at present being investigated.

We thank Drs. William C. Dement, Frederick Snyder and Norman Q. Brill for advice and Mrs. Kathryn S. Carter for assistance.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Tuesday, December 29

INSTITUTE OF BIOLOGY (in the Lecture Hall of the British Museum (Natural History), Cromwell Road, London, S.W.7), at 11.30 a.m.—Dr. L. Broadbent: "Being a Biologist" (Christmas Lecture for Children).

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 2.30 p.m.—Mr. Peter Hall: "London 2000" (Christmas Lecture for Children).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 3 p.m.—Dr. Desmond Morris: "Animal Behaviour". (The one hundred and thirty-fifth course of six lectures adapted to a juvenile auditory. Further lectures on December 31, January 2, 5, 7, 9.)

Wednesday, December 30

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 2.30 p.m.—Mr. Peter Scott: "Wild Life in Danger" (Christmas Lecture for Children).

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Prof. S. Tolansky, F.R.S.: "The Curiosities of Light" (Dr. Mann Juvenile Lecture).

Thursday, December 31

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Meeting on "Fossil Spores" with contributions by Dr. A. R. H. Martin, Dr. W. G. Chaloner, Mr. J. M. Pettitt, Dr. G. A. Leisman, Dr. J. Richardson and Dr. K. L. Alvin.

Friday, January 1

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 3 p.m.—Prof. E. W. Gilbert: "Andrew John Herbertson, 1865–1915".

Friday, January 1—Monday, January 4

GEOGRAPHICAL ASSOCIATION (at the London School of Economics, Houghton Street, London, W.C.2)—Annual Conference.

Monday, January 4

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. R. Knight and Mr. K. Hambleton: "The Present State of Gallium Arsenide Technology".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—Geographical Films.

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. B. E. Moody: "Recent Developments in Container Glass".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

PHYSICIST or ELECTRICAL ENGINEER, ASSISTANT EXPERIMENTAL OFFICER grade (with a degree, Dip. Tech. or H.N.C. in an appropriate subject) for design work on lighting and air conditioning facilities needed for the study of plant growth—The Secretary, National Institute of Agricultural Engineering, Wrest Park, Silsoe, Bedford, quoting Ref. N/64/ECD/19 (December 31).

VICE-PRINCIPAL (graduate with good industrial and teaching experience, and administrative experience in the field of further education, for example, as head of a department in a technical college) of the South-West Essex Technical College and School of Art, Forest Road, Walthamstow—Chief Education Officer, County Hall, Chelmsford, Essex (January 4).

LECTURER IN THE DEPARTMENT OF GEOGRAPHY, University of Tasmania—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, January 5).

LECTURER (with special interests in meteorology and climatology and qualifications which include a knowledge of physical meteorology) IN THE DEPARTMENT OF ENVIRONMENTAL STUDIES—The Secretary, University of Lancaster, Bailrigg House, Lancaster (January 7).

LECTURER or ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, University of York, Heslington, York (January 8).

MICROBIOLOGIST (with an honours degree in science majoring in bacteriology, or dairy science or equivalent, and preferably some postgraduate bacteriology research experience) IN THE DAIRY BACTERIOLOGY DEPARTMENT—The Director, An Foras Taluntais (The Agricultural Institute), 33 Merrion Road, Dublin 4, Republic of Ireland (January 11).

ASSISTANT LECTURER (with a good honours degree) IN GEOGRAPHY—The Registrar, Room (T), The University, Hull (January 12).

LECTURER or ASSISTANT LECTURER (graduate in economics, statistics or mathematics, and an interest in the application of statistics and mathematics in economics and other social sciences) IN STATISTICS with special reference to econometrics—The Assistant Secretary, The London School of Economics and Political Science, Houghton Street, London, W.C.2 (January 12).

LECTURER IN THE DEPARTMENT OF THEORETICAL PHYSICS—The Registrar, The University, Liverpool, quoting Ref. CV/377 (January 15).

RESEARCH FELLOW IN PURE MATHEMATICS—The Master, Clare College, Cambridge (January 15).

SENIOR TECHNICIAN or TECHNICIAN IN THE DEPARTMENT OF VETERINARY PHYSIOLOGY AND BIOCHEMISTRY, University of Khartoum—The Registrar, University of Khartoum, c/o The Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 15).

EXPERIENCED MICROBIOLOGIST (with veterinary qualifications) to assist in the expansion of work on avian respiratory infections; an EXPERIENCED PHYSIOLOGIST or BIOCHEMIST (preferably with a veterinary qualification) to assist in the expansion of the Physiology/Biochemistry Department; and a VIROLOGIST (experienced in tissue culture techniques) to assist in work on avian respiratory infections—The Secretary, Houghton Poultry Research Station, Houghton, Huntingdon (January 15).

LECTURER IN BIOCHEMISTRY—The Principal, Cambridgeshire College of Arts and Technology, Collier Road, Cambridge (January 20).

LECTURER or ASSISTANT LECTURER (preferably with recent industrial experience) IN AIRCRAFT DESIGN—The Deputy Secretary, The University, Southampton (January 20).

LECTURER (preferably with an interest in applied nuclear physics), and an ASSISTANT LECTURER IN THE DEPARTMENT OF APPLIED PHYSICS—The Registrar, Room (X), The University, Hull (January 20).

ASSISTANT LECTURER IN THE DEPARTMENT OF PSYCHOLOGY—The Registrar, University College of North Wales, Bangor, North Wales (January 20).

LECTURERS or ASSISTANT LECTURERS (2) IN THE DEPARTMENT OF APPLIED MATHEMATICS (a research interest in fluid dynamics is desirable for one of these posts)—The Registrar, University College of North Wales, Bangor, North Wales (January 20).

ASSISTANT LECTURERS/LECTURERS IN THE DEPARTMENT OF GEOGRAPHY in the following fields: polar or marine studies; geography of Asia or Mediterranean Lands; climatology and meteorology; history of cartography—The Secretary, The University, Aberdeen (January 22).

LECTURER IN PREHISTORIC ARCHAEOLOGY (primarily in the Palaeolithic and Mesolithic)—The Secretary of Faculties, University Registry, Oxford (January 23).

READER, and LECTURERS or ASSISTANT LECTURERS (3) IN THE DEPARTMENT OF ZOOLOGY—The Deputy Secretary, The University, Southampton (January 23).

SENIOR LECTURER or LECTURER (preferably with considerable experience in the fields of ecology, nature conservation and/or ethology) IN THE DEPARTMENT OF ZOOLOGY, University of Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 23).

LECTURERS or ASSISTANT LECTURERS IN MATHEMATICS at the University of Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 33 Bedford Place, London, W.C.1 (January 25).

CHAIR OF PHYSICAL CHEMISTRY—The Registrary, University Registry, The Old Schools, Cambridge, marking envelope "Confidential" (January 26).

CHAIR OF ZOOLOGY—The Registrary, University Registry, The Old Schools, Cambridge, marking envelope "Confidential" (January 26).

SENIOR LECTURER (with a degree in science or engineering, preferably a doctorate, experience in the maintenance and operation of electron microscopes, and a wide knowledge of electron microscopy techniques, including application to biological, mineralic and metallurgical materials) IN ELECTRON MICROSCOPY at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, January 29).

LECTURER IN CLINICAL BACTERIOLOGY IN THE UNIVERSITY DEPARTMENT OF BACTERIOLOGY with an honorary appointment as Senior Registrar in the United Bristol Hospitals—The Registrar, The University, Senate House, Bristol, 2 (January 31).

LECTURERS (with postgraduate experience in experimental or theoretical solid-state physics) IN PHYSICS—The Secretary, University of Lancaster, Bailrigg House, Lancaster (January 31).

CHAIR OF SOCIOLOGY—The Secretary, The University, Edinburgh (January 31).

LECTURER or ASSISTANT LECTURER (with an honours degree in a biological subject or in physiology) IN BIOLOGICAL OCEANOGRAPHY; and a LECTURER or ASSISTANT LECTURER (with an honours degree in mathematics, electronics or a physical science) IN PHYSICAL OCEANOGRAPHY—The Deputy Secretary, The University, Southampton (February 1).

LECTURER or ASSISTANT LECTURER (with an honours degree in engineering or physics and experience in industrial acoustics) IN INDUSTRIAL ACOUSTICS at the Institute of Sound and Vibration Research—The Deputy Secretary, The University, Southampton (February 1).

PRINCIPAL (with high qualifications and wide administrative experience)—The Clerk and Treasurer, Paisley College of Technology, High Street, Paisley, Renfrewshire, Scotland (February 1).

RESEARCH FELLOW IN PURE MATHEMATICS—The Master, Corpus Christi College, Cambridge (February 1).

LECTURER (preferably with experience and interests in general psychology together with competence in the field of experimental psychology) IN PSYCHOLOGY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, February 5).

POST-DOCTORAL RESEARCH FELLOWS (2) IN CHEMICAL CRYSTALLOGRAPHY, to join a Group which is carrying out systematic X-ray crystallographic studies of biochemically interesting metal-peptide complexes—The Registrar, University of Sydney, Sydney, New South Wales, Australia (February 8).

IMPERIAL CHEMICAL INDUSTRIES RESEARCH FELLOWS IN PHYSICS, CHEMISTRY, BIOCHEMISTRY, ENGINEERING, METALLURGY AND PHARMACOLOGY or any related subjects—The Registrar, The University, Liverpool, quoting Ref. CV/375/N (February 13).

ISAAC WOLFSON PROFESSOR OF METALLURGY—The Registrar, University Registry, Oxford (February 13).

PROFESSOR OF ELEMENTARY PARTICLE PHYSICS—The Registrar, University Registry, Oxford (February 13).

CHAIR OF GEOGRAPHY—The Registrary, University Registry, The Old Schools, Cambridge, marking envelope "Confidential" (February 18).

SENIOR LECTURER (with a higher degree in physics with suitable research and teaching experience, and preferably with experimental experience in one of the following fields: solid state physics, X-ray crystallography, infra-red spectroscopy, polymer physics, or low-temperature physics) IN PHYSICS—The Registrar, New Asia College, Chinese University of Hong Kong, Farm Road, Kowloon, Hong Kong (February 28).

DIRECTOR OF THE COMPUTER LABORATORY, University of Auckland, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, March 1).

ASSISTANT LECTURER and a COLLEGE LECTURER (with the degree of M.B. and Ph.D. or equivalent) IN THE DEPARTMENT OF PHYSIOLOGY—The Secretary and Bursar, University College, Dublin, Republic of Ireland.

ASSISTANT LECTURER (with a good class honours degree, and preferably research or industrial experience) IN PHYSICAL ORGANIC CHEMISTRY—The Academic Registrar, Hatfield College of Technology, Hatfield, Hertfordshire.

DIRECTOR OF RESEARCH FOR THE FISHERIES RESEARCH DIVISION, Wellington—The Secretary, Marine Department, P.O. Box 2395, Wellington, New Zealand.

ELECTRON-MICROSCOPE TECHNICIAN (aged between 25 and 35 with experience in physical and biological work and with a sound knowledge of replica, embedding and sectioning techniques) to take charge of the operation and maintenance of a Siemens Elmiskop Mk. I and ancillary equipment—

The Director of Research, The Natural Rubber Producers' Research Association, Welwyn Garden City, Hertfordshire.

EXPERIMENTAL OFFICER (preferably with experience of chromatographic, electrophoretic and radioactive tracer techniques as applied to nucleic acids and proteins) IN THE BIOCHEMISTRY DEPARTMENT, for work concerned with the structure and mechanism of replication of animal viruses—The Secretary, Animal Virus Research Institute, Pirbright, Surrey.

IMMUNOLOGIST (with general experience in microbial immunology, and preferably with a medical qualification) at the Mill Hill Laboratories of the Imperial Cancer Research Fund—The Secretary, Imperial Cancer Research Fund, Lincoln's Inn Fields, London, W.C.2.

INVESTIGATOR (graduate or equivalent) to join research staff initially for work on the evaluation of dust-sampling instruments for industrial use which will involve laboratory investigations and practical trials in industry—The Director, The British Cast Iron Research Association, Bordesley Hall, Alvechurch, Birmingham.

LECTURER IN CIVIL ENGINEERING—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 28/G.

ORGANIC CHEMIST (Ph.D. with experience of the phosphines, phthalocyanines and/or similar substances) to investigate the reactions of their metal complexes—Prof. J. Chatt, Agricultural Research Council, Unit of Nitrogen Fixation, University of Sussex, Brighton, Sussex.

PLANT PATHOLOGIST (national of the United Kingdom or the Republic of Ireland, with a degree in botany of natural science, and preferably specialist training or postgraduate experience in mycology, virology or plant pathology) in Zambia, to investigate major diseases of crops of economic importance and to make recommendations based on experimental results—The Appointments Officer, Room 301, Ministry of Overseas Development, Eland House, Stag Place, London, S.W.1, quoting RC213/132/07.

PRINCIPAL LECTURER IN PSYCHOLOGY—The Director, Huddersfield Training College for Technical Teachers, Holly Bank Road, Lindley, Huddersfield.

PRINCIPAL SCIENTIFIC OFFICER (physicist or physical chemist) to work on the structure and physical properties of animal viruses and the intracellular processes involved in their replication—The Secretary, Animal Virus Research Institute, Pirbright, Surrey.

PROFESSOR OF POLYMER CHEMISTRY; a PROFESSOR OR ASSOCIATE PROFESSOR (with established research interests in mass spectroscopy) OF PHYSICAL CHEMISTRY; and ASSISTANT PROFESSORS OF ANALYTICAL, INORGANIC AND PHYSICAL CHEMISTRY—The Chairman, Department of Chemistry, McGill University, Montreal, Quebec, Canada.

RESEARCH ASSISTANT (graduate with an honours degree in botany or agricultural botany) to assist with an investigation of the factors which determine the weed seed content of crop seeds—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

RESEARCH STUDENT (with a good honours degree or holder of G.R.I.C. at an equivalent level) IN THE DEPARTMENT OF CHEMISTRY, for research in the field of the synthesis of heterocyclic compounds or potential pharmacological activity—The Registrar, The University, Hull.

RESEARCH STUDENTS (with a good honours degree or a higher degree or expecting to obtain such a degree by next July) in both theoretical and experimental physics—Prof. L. R. B. Elton, Head of the Department of Physics, Battersea College of Technology, London, S.W.11.

SCIENTIFIC OFFICER OR SENIOR SCIENTIFIC OFFICER (with a first- or good second-class honours degree in chemistry, metallurgy or physics, and preferably experience in the field of oxidation) to join a team interested in basic studies related to the oxidation of metals and ceramics—The Personnel Department, Atomic Energy Research Establishment, Harwell, Didcot, Berkshire.

SCIENTIST (graduate in chemistry or biochemistry) in the Radioisotope Unit, to be concerned with developing new diagnostic radioisotope procedures, and to assist in clinical research involving the use of radioactive isotopes—The Administrator, Royal Marsden Hospital, Surrey Branch, Downs Road, Sutton, Surrey.

Barnett, Prof. Donald Mackay and Prof. O. R. Frisch. Pp. 56. 4*s*. 6*d*. A New Kind of Physics: a Broadcast Symposium. By Dr. Dennis Sciama, Dr. C. W. Kilmister, Prof. Fred Hoyle and Prof. Hermann Bondi. Pp. 32. 3*s*. (London: British Broadcasting Corporation, 1964.) [3010

National Council for Quality and Reliability. Third Annual Report 1963–64. Pp. 19. (London: National Council for Quality and Reliability, 1964.) [3010

Institute of Biology. Biology as a Career. Pp. 44. (London: Institute of Biology, 1964.) 3*s*. 6*d*. [3010

An Annotated Bibliography of Memoirs and Papers on the Soils of the British Isles. Part 1: The Classification, Morphology, Distribution and Reclamation of British Soils. Edited and Compiled by B. T. Bunting. Pp. iv+100. (London: Geomorphological Abstracts, Department of Geography, London School of Economics, 1964.) 10*s*. [3010

Society for the Promotion of Nature Reserves. Handbook 1964: Forty-Seventh Annual Report, year ending 31st March, 1964. Pp. 56+2 plates. (London: Society for the Promotion of Nature Reserves, c/o British Museum (Natural History), 1964.) 10*s*. [3010

The International Nickel Company (Mond), Ltd. Nickel-Alkaline Accumulators. Pp. 24. (London: The International Nickel Company (Mond), Ltd., 1964.) [3010

Year Book of the Royal Society of Edinburgh, 1964 (Session 1962–1963). Pp. 136. (Edinburgh: Royal Society of Edinburgh, 1964.) 20*s*.; 3.50 dollars. [3010

The Chemistry of Proteins. By R. J. Taylor. (A Unilever Educational Booklet—Advanced Series.) Pp. 43. (London: Unilever, Ltd., 1964.) [3010

University College of Wales. Memorandum No. 7: Synopsis of Discussions held on March 18th, 1964, on the subject of Major Weather Hazards Affecting British Agriculture. Edited by James A. Taylor. Pp. 55. (Aberystwyth: University College of Wales, 1964.) [3010

Bulletin of the British Museum (Natural History). Entomology. Vol. 15, No. 7: Revisional Notes on African *Charaxes* (Lepidoptera: Nymphalidae). Part 2. By V. G. L. van Someren. Pp. 181–235+23 plates. (London: British Museum (Natural History), 1964.) 63*s*. [211

Imperial College of Science and Technology (University of London). Research Report of the City and Guilds College, 1961–64. Pp. 108. (London: City and Guilds College, 1964.) [211

Other Countries

North Atlantic Treaty Organization: Advisory Group for Aeronautical Research and Development. AGARD—General Information 1964. Pp. 21. (Paris: Advisory Group for Aeronautical Research and Development, NATO, 1964.) [311

Institut Royal Météorologique de Belgique. Contributions, No. 92: Introduction à l'Étude du Bioclimat. Par Dr. L. Poncelet. Pp. 5. Publications, Série A, No. 50: Études Microclimatiques, Opuscule III. A: Microclimat d'Une Peupleraie. Zoutleeuw (Léau), 1954–1955. Enregistrement des Températures à l'Intérieur et dans le Voisinage d'Un *Populus robusta*. Par Dr. S. M. de Backer. B: Aperçu Climatologique du Nord Est de la Hesbaye. Par Dr. A. Vandenplas. Pp. 21+14 planches. (Uccle-Bruxelles: Institut Royal Météorologique de Belgique, 1964.) [311

Proceedings of the International Conference on Cosmic Rays, Jaipur, December 1963. Vol. 1: Solar Particles and Sun-Earth Relations. Pp. 265. (Colaba, Bombay: Tata Institute of Fundamental Research, 1964.) [311

United States Department of the Interior: Geological Survey. Professional Paper 260–CC, DD, EE, FF, GG, HH: Bikini and Nearby Atolls, Marshall Islands. By Ryth Todd *et al*. Pp. iii+1067–1131+plates 289–303. Professional Paper 313–G: Geology of the Killik-Itkillik Region, Alaska. By William W. Patton, Jr., and I. L. Tailleur. Pp. iv+409–500+plates 50 and 51. Professional Paper 331–B: Neogastropoda, Opisthobranchia and Basommatophora from the Ripley, Owl Creek, and Prairie Bluff Formations. By Normal F. Sohl. Pp. 153–344+plates 19–52. Professional Paper 391–C: Quantitative Interpretation of Mineralogical Composition from X-ray and Chemical Data for the Pierre Shale. By Leonard G. Schultz. Pp. iii+31+plate 1. Professional Paper 483–C: Marine Jurassic Pelecypods from Central and Southern Utah. By Ralph W. Imley. Pp. iii+42+plates 1–4. Professional Paper 403–A: General Geology of Guam. By Joshua I. Tracey, Jr., Seymour O. Schlanger, John T. Stark, David B. Doan and Harold G. May. Pp. iv+104+plates 1–3. Professional Paper 418–B: Middle Bajocian Ammonites from the Cook Inlet Region, Alaska. By Ralph W. Imlay. Pp. iv+91+plates 1–29. Professional Paper 442: Water Resources of the Upper Colorado River Basin—Basic Data. By W. V. Iorns, C. H. Hembree, D. A. Phoenix and G. L. Oakland. Pp. viii+1036+plates 1–4. (Washington, D.C.: Government Printing Office, 1964.) [311

United States Department of the Interior: Geological Survey. Professional Paper 453: Geology of the Abajo Mountains Area, San Juan County, Utah. By Irving J. Witkind. Pp. v+110+plates 1–5. Professional Paper 454–L: Stratigraphy of the Niobrara Formation at Pueblo, Colorado. By Glenn R. Scott and William A. Cobban. Pp. iii+29+plates 1–11. Professional Paper 462–A: Discharge of Sands and Mean-Velocity Relationships in Sand-Bed Streams. By B. R. Colby. Pp. vii+47. Professional Paper 474–D: The 1961 Eruption of Kilauea Volcano, Hawaii. By D. H. Richter, W. U. Ault, J. P. Eaton and J. G. Moore. Pp. iii+34. Professional Paper 483–A: California Carboniferous Cephalopods. By Mackenzie Gordon, Jr. Pp. iii+27+plates 1–4. Professional Paper 483–D: Upper Jurassic Mollusks from Eastern Oregon and Western Idaho. By Ralph W. Imlay. Pp. iii+21+plates 1–4. Professional Paper 501: Geological Survey Research 1964, Chapter B. Pp. vi+190. (Washington, D.C.: Government Printing Office, 1964.) [311

United States Department of Agriculture, in co-operation with Florida Agricultural Experiment Station. Technical Bulletin No. 1295: The Tabanidae (Diptera) of Florida. By C. M. Jones and Darrell W. Anthony. Pp. ii+85. (Washington, D.C.: Government Printing Office, 1964.) [311
